The PBR for the western Arctic bowhead whale population was based on a minimum population estimate of 7738, a rate of increase of 3.2% (with a harvest, so an R_{max} of 4% was used), and a recovery factor of 0.5 (because the population is increasing in the presence of a known take). These result in a PBR of 77 animals ($7738 \times 0.02 \times 0.5$). The development of a PBR for this stock is required by the MMPA even though the Alaska Eskimo subsistence harvest is managed under the authority of the IWC. Thus, the IWC quota takes precedence over the PBR estimate. Assessments by the IWC were based on Bayesian analyses using age- and sex-structured population models. A reference set of prior distributions was developed for the parameters MSYL, MSYR (a measure of productivity), transition age from juvenile to adult mortality, K, age at sexual maturity, juvenile and adult survival rate, and maximum fecundity rate. Bayesian posterior distributions gave estimates of K from 11,000 to 17,000 and RY from 123 to 276. Thus the smallest RY value is larger than the current IWC maximum strike limit of 82, which should allow the population to increase.

B. Pinnipeds

Commercial harvests of subadult male northern fur seals (*Callorhinus ursinus*) took place on the Pribilof Islands from the time of their discovery in 1786 until 1984. After 1918, the harvest was conducted under the auspices of the Treaty on the Conservation of the Northern Fur Seal. The renegotiated treaty of 1957 provided a vehicle for cooperative research among scientists of the party nations and specified that the population was to be managed to obtain "maximum sustained productivity." Attempts have been made to fit spawner-recruit models to fur seal data and to use them to set the harvest, but these methods largely failed probably due to high variability in year class survival. Using data of numbers of young of the year (pups), counted earlier in the century and the pattern of harvests, it was estimated that the harvests, on average, took about 30% of the number of male seals born or about 15% of the total seals born. When managers of the Pribilof herd learned that age at first reproduction of the Russian herd was, on average, 1 year younger than the Pribilof herd, they justified a large reduction of females in the Pribilof population with the idea that with a lower herd density, age at first reproduction would decrease to the level of the Western Pacific population, and a sustainable harvest of the same size would be obtained from a reduced population. That idea was tried and failed, perhaps because the harvesting regime preferentially killed those females that tended to reproduce at a younger age. At present, there is no commercial harvest, but a subsistence take for food is permitted. The maximum size of the subsistence take is set by the PBR approach at about 18,000 animals, well above the current harvest levels of 800–1000 animals.

The Northwest Atlantic harp seal (*Pagophilus groenlandicus*) population in Canada is currently subject to a harvest. Approximately 450,000 animals (mostly young of the year) were removed from the population each year since 1995. The total population of harp seals (currently estimated at 4–6 million animals) is estimated from a population model based on data of pup production, age-specific reproductive rates, size and age of the commercial harvest, and estimates of size and age of bycatch taken in nearshore fisheries. The model also estimates annual survival rates (assumed to be constant) of adults and juveniles. Confidence intervals for the total population are obtained using a parametric bootstrap procedure that attempts to take account of the uncertainties in all the inputs to the population model.

The replacement harvest for the next year is estimated by projecting current population estimates forward for 1 year, varying the harvest until a constant total population is obtained. The uncertainty in this estimate is determined using a similar bootstrap procedure as in the population model. Using this method, Canadian scientists estimate the replacement yield to be 540,000 (SE = 87,000) animals, or at about 10% of the total population estimate.

Stock Identity

JOHN Y. WANG
FormosaCetus Research and Conservation Group, Thornhill, Ontario, Canada

I. Importance of Stock Identity

Determining how a species is divided into stocks (the term stocks is used to refer to biological stocks rather than management stocks; see later) is fundamental to the conservation of marine mammals. Because evolutionary processes act at the intraspecific level, genetic differences and locally adaptive characters will accumulate in stocks over time. This reservoir of genetic and phenotypic diversity increases a species' ability to persist through environmental changes. Thus, one of the main goals in conservation is to preserve the evolutionary potential of species by maintaining the diversity found in stocks. Another important goal is to maintain species as functioning elements in their ecosystem by preventing regional overexploitation and depletion. Consequently, knowledge of stock structure of species is integral for developing effective management programs to achieve these goals.

The greatest threats to the survival of marine mammals are human activities. Most species experience various levels and kinds of anthropogenic threats in different regions and all exhibit life history characteristics (i.e., long-lived, low fecundity, late age of maturity) that make them especially susceptible to these threats. In order to assess the impact of human activities on marine mammals, it is crucial to identify stocks accurately, establish where the stock boundaries exist, and determine the permeability of the boundaries to genetic exchange with other stocks. This information will influence how the biological data needed for assessments are collected and interpreted and how management plans are designed. Inaccurate stock designations can lead to either unnecessary regulation(s) of fisheries or fallacious management that result in the depletion of a stock and its accompanying genetic material. For example, managing two distinct stocks as one because of a failure to distinguish the two stocks might lead to the depletion of one of the stocks.

Understanding stock structure can also help in streamlining the design of other studies, providing insights into evolution and monitoring ILLEGAL ACTIVITIES [e.g., DNA analysis of cetacean meat products from Japanese markets found species that were prohibited from sale (see Baker and Palumbi, 1994)]. Therefore, it is not surprising that much effort has been directed toward identifying stocks of marine mammals. However, the task remains problematic with two major difficulties: (1) semantic uncertainty and disagreement in the definition of "stock" and (2) studying stock identity with incomplete biological knowledge.

II. Definition of Stock

The term "stock" has been used to refer to both biological and management entities (although in many cases, they are combined or inseparable). A management stock is a group of conspecific individuals that are managed separately. It is very much dependent on the goals of managers and may not be based on biological discontinuities (e.g., International Whaling Commission management stock designations for baleen whales). With the exception of the definition by Moritz (1994), who described a "management unit" (MU) (which he synonymized with "stock" and appears to be equivalent to management stock) as having significant differences in allele frequencies at nuclear or mitochondrial DNA loci, the criteria for determining management stocks may have little to no biological rationale or consistency and are influenced greatly by political interests. Nevertheless, management stocks have been used widely due to the paucity of biological information and will likely continue to play an important role in conservation. Developments in management strategies for situations with incomplete biological information should improve the success of conservation programs (e.g., Taylor, 1997). Although management stocks offer more flexibility in the sense that they can still

be the focus of management programs without evidence of biological distinctiveness, conservation goals (e.g., maintaining genetic diversity) are more likely to be achieved if stocks are based on biological data. Therefore, this article focuses mainly on biological stocks.

Biological stocks are characterized by no or low levels of genetic exchange (which means that members of a biological stock tend to interbreed with each other more often than with other individuals). An entity with this property has also been called a population, subpopulation, evolutionary significant unit (ESU), deme, and subspecies (the only intraspecific taxon recognized by the International Commission on Zoological Nomenclature). When gene flow between two groups is absent, there is usually no disagreement that they represent separate biological stocks. However, it is more typical that some level of genetic exchange exists. Even low levels of genetic exchange can obscure stock boundaries and complicate the task of discriminating biological stocks. Although there is no consensus on the threshold level of gene flow above which stock status is no longer recognized, several approaches have been developed to make the identification of biological stocks more objective and explicit.

III. Stock Identification Approaches

Defining stocks is linked inextricably with defining species. There are many concepts that propose species definitions but those advocated most commonly today include biological, evolutionary, and phylogenetic species concepts (for a detailed overview of these and other concepts, see Sites and Crandall, 1997; King, 1993). However, because these concepts all have major limitations, agreement on the best species definition still eludes biologists. Like the species concepts, each approach to stock identification has limitations and weaknesses. In addition, defining stocks can be influenced, and therefore complicated further, by the goals of conservation and legislation. For example, one of the goals of the U.S. Endangered Species Act (ESA) is to decrease the loss of genetic variation. Thus, for this purpose, defining stocks using genetic criteria [e.g., the ESU of Moritz (1994)] is a reasonable proposal [however, see Pennock and Dimmick (1997) and Dimmick *et al.* (1999)]. Unlike the ESA, the U.S. Marine Mammal Protection Act (MMPA) endeavors to keep biological stocks at or beyond their optimum sustainable levels and functioning in their ecological roles. To accomplish the intent of this legislation, defining conservation units will also require demographic information.

There are several operational approaches to stock identification. Whereas some approaches are clear extensions of certain species concepts, the theoretical basis of others may be less explicit or embedded within the methodology. Brief descriptions of the approaches used most commonly are presented.

Morphological characters have been the main evidence for delineating stocks. Because differences between stocks are generally less obvious than between species, examination of a large series of specimens is recommended for the identification of stocks under this approach. However, for most marine mammal species, it is difficult, if not impossible, to obtain a large number of specimens for analysis.

The "phylogeographic" approach proposed by Dizon *et al.* (1992) determines the likelihood that a group of organisms is an ESU. The determination is based on distribution, population response (including demography, behavior, vocalizations), and phenotypic and genotypic information, all of which serve as proxies for reproductive isolation (the essence of the biological species concept). Groups most likely to be ESUs have clear geographic and genetic separation and are assigned to "category I." "Category II" units are characterized by clear genetic separation but little to no geographic partitioning. Units with little genetic differentiation but isolated geographically from other conspecifics define "category III." "Category IV" units are the least likely to be ESUs because they are separated neither geographically nor genetically from other units. This approach has been described as being unwieldy, but it is explicit, transparent, and has performed well. It also seems to provide the most flexibility in stock delineation because several kinds of evidence are used and it offers more than a simple dichotomy for the mosaic of variation present. In addition, by considering information on distribution and population responses, it is much better than the other approaches at detecting recently diverged stocks.

Moritz (1994) proposed definitions for ESU and MU that differ from those of the phylogeographic approach. His definition of ESUs requires these entities to be reciprocally monophyletic (i.e., to have diagnostic differences) in mitochondrial DNA (mtDNA) and significant divergence in nuclear DNA allele frequencies, whereas MUs are defined by significant divergence in either mtDNA or nuclear DNA allele frequencies (irrespective of the distinctiveness of the alleles). Because these definitions are based solely on DNA patterns, they cannot be realized with nonmolecular characters and therefore have limited application. Although DNA information may be more direct for determining whether genetic differences exist (some phenotypic characters can be plastic and influenced by environmental factors), it is not always available and stock differences in phenotypic characters may be established more rapidly after divergence (e.g., demographic response).

The "phylogenetic" approach for defining ESU was advocated by Vogler and DeSalle (1994). Their procedure for recognizing ESUs is similar to how species are delimited under the phylogenetic species concept. Only heritable genetic, morphological, ecological, or behavioral characters are analyzed. An entity is deemed an ESU if it differs from all other entities in having a unique character or a diagnostic combination of characters. However, it is unclear how the definitions of ESU and species differ with this approach, and the process of determining useful characters may require expert knowledge and can be operationally complex.

The "character concordance" approach (Avise and Ball, 1990; Grady and Quattro, 1999) suggests that a group of individuals sharing a common evolutionary history should share characters that are unique to the group and that the level of concordance among independent, shared characters should increase with increasing divergence time. Therefore, high concordance would be strong support for distinctiveness. When concordance is incomplete, the weight of the evidence governs the decision on stock status. Because there are no clear procedural guidelines for interpreting discordant evidence, decisions may be complicated

and subjective. Furthermore, many independent characters evolve at different rates so a lack of concordance may be expected for groups that diverged recently. Therefore, this approach may not be effective in identifying recently separated stocks.

Regardless of the approach one decides to use, it is important that clear hypotheses are stated so that interpretation of the results can be objective and divorced from philosophical or conceptual issues. It is also important that the interpretation of data is within the limitations of the hypotheses being tested. For example, if the results of a study do not support distinct units, then the statistical ability (or power) of the study to detect separate units should be examined. With adequate power, the appropriate conclusion would be that differences in the characters examined were not detected rather than that differences do not exist between the units being studied. Without sufficient power, conclusions regarding stock structure would be premature and should not be made. Finally, it may be tempting to combine units when evidence for separating the units is not found. However, this conclusion could be erroneous, is not risk averse, and should be avoided.

In situations where essentially no biological stock information exists, the participants of a workshop on the genetics of marine mammals recommended that the smallest area where exploitation occurs be recognized as a stock (management stock). However, they also cautioned that in certain circumstances (e.g., migratory stocks that experience exploitation in several fisheries in different areas or seasons), this strategy may not be precautionary (Dizon *et al.*, 1997). Therefore, the suitability of this approach should be assessed for each case and only used temporarily while immediate attention is directed at studying biological stock structure.

IV. Analytical Techniques

Several types of information have contributed to our understanding of marine mammal stocks. Which analytical techniques are adopted depends on which stock definition and identification approach are followed.

Analyses of phenotypic characters have dominated this task. Comparisons of osteology, morphology, and pigmentation have contributed the most to stock identification because these characters provide tangible evidence of distinctness. Also, increased computing capabilities have made multivariate analyses of large data sets simple and quick. However, there are few species (and even fewer stocks) for which data from a large series of specimens can be examined because specimens are difficult and expensive to obtain, prepare, and store and some characters can be affected greatly by the condition of the specimen (e.g., decomposition and external morphology; postmortem changes in pigmentation).

Increasingly, attention has been shifting toward molecular characters. Protein analyses were important for stock identification but have become obsolete with the development of efficient DNA technology. Presently, most conclusions regarding stock status are not accepted fully until DNA has been analyzed as well.

Because the properties of mammalian mtDNA are fairly well understood, analysis of mtDNA has dominated molecular studies of marine mammal stocks. For many marine mammal conservation goals, mtDNA evidence is sufficient for designating management stocks [for more details, see Dizon *et al.* (1997)], whereas for designating biological stocks, evidence from characters that are heritable from both parents would be required. Direct analyses of nuclear DNA, which is inherited from both parents, are becoming more common.

Most marine mammal species do not have uniform distributions. There are usually high concentration areas that are separated by areas of low to no concentration of conspecifics. Thus, distribution can provide a first approximation of where stock boundaries may exist. Based on heterogeneous distributions, seasonality of occurrence, oceanographic features (e.g., barriers, water currents, temperature), and geographic distance between areas of high abundance, provisional stocks can be proposed for further studies to test. However, distributional data should always be interpreted in conjunction with additional biological knowledge (e.g., daily and seasonal movement patterns, philopatric behavior).

Most distinct stocks are separated geographically or temporally. Therefore, each stock experiences unique ambient conditions (e.g., differential environmental stresses, food quality or availability, exploitation). Adaptive responses to different conditions may be expressed demographically or ecologically. Different demographic profiles in two groups would be strong evidence of noninterbreeding stocks. Also, demographic differences can reveal recently isolated stocks that have yet to develop genetic or phenotypic distinctiveness. However, to obtain accurate demographic information, a large data set must be analyzed. Because other techniques can address stock identity more directly and efficiently, few studies employ demographic analysis for delineating stocks. If available, demographic information should also be analyzed, especially if stock status based on molecular and phenotypic evidence is uncertain.

Many studies have proposed stocks using analyses of ecological differences. Prey preference, parasitology, pollutant loads, stable isotope ratios, and fatty acid signatures are some of the ecological information used most commonly. Although ecological studies provide another line of evidence for understanding stocks, they act only as proxies for genetic and demographic separation.

V. Complications

Even if there was agreement on a single stock definition and multiple techniques were used, defining stocks would still not be a trivial task. Many situations can obscure and complicate our attempts to delineate stocks, including taxonomic uncertainty; genetic exchange; clinal variation; dispersal and differences between sexes in philopatric behavior; diversity in mating strategies; habitat shifts (e.g., occasional environmental fluctuations may bring stocks that are usually separated geographically into contact and allow interbreeding); fragmentation and genetic bottlenecks resulting from exploitation; mixed stocks; social structure; and short-term and seasonal movements, sometimes across international boundaries. Without knowledge of and consideration for these (and other) attributes, conclusions about stock structure can be compromised.

With so many complications, it is not surprising that the biological stock structure of most marine mammal species (even those that were exploited heavily by commercial harvesting) remains uncertain. However, multidisciplinary techniques, technological advancements, and continued attention should allow us to make rapid progress in identifying biological stocks of marine mammals and to design more effective management programs in the absence of essential biological information.

Stranding

William F. Perrin
Southwest Fisheries Science Center, La Jolla, California

Joseph R. Geraci
National Aquarium in Baltimore, Maryland

tranded whales have fascinated us through history (Fig. 1). Why do marine mammals strand, what can we learn from their misfortune, and what can we do about it?

I. Why Do Marine Mammals Strand?

Animals that die or become enfeebled at sea of course may be brought passively to shore by wind and wave action. More intriguing are those cases where marine mammals in distress purposely come ashore. A stranded animal when returned to the water may deliberately strand again. This is very frustrating to those who are trying to "rescue" it. It must be understood that an animal may have stranded because it has decided that it cannot keep itself afloat and survive at sea. Thus, deliberate stranding may represent an effort to keep breathing, whatever the ultimate cost. While this may not be adaptive behavior in evolutionary terms because nearly all stranded animals die if unassisted, given the alternative of equally certain but earlier death, the consideration may be moot. A will to survive is adaptive in general, even if not effective in this circumstance.

The natural and unnatural causes of death and disablement leading to single strandings are many: environmental conditions such as anomalously low sea temperature or ice entrapment, parasites, disease, biotoxins, ENTANGLEMENT associated with fisheries, starvation due to decreased food supply, collisions with vessels, contaminants, oil spills, and death or direct injury inflicted by predators, other marine mammals, or at the hands of humans (Geraci and Lounsbury, 1993). Determining the cause of a stranding can be very difficult, even when one is not dealing with a decomposed carcass; symptoms and pathology may be obscure, and two or more factors may be operating simultaneously. Animals that strand in a cluster over a period of a few days may be victims of poisoning, infectious diseases, intensive local fisheries operations, or unusual environmental events. By the time the strandings are investigated, the ultimate cause may no longer be evident.

Certain patterns are exhibited in the strandings of particular species related to their distribution, migrations, and reproduction (Geraci and Lounsbury, 1993). For example, newborn gray whales, *Eschrichtius robustus,* are likely to come ashore in the lagoons of Baja California only during the winter calving season. For all cetaceans, the mother/calf bond is very strong and may continue after lactation ceases. If they come ashore together, it may be impossible to determine who led the way. Young juvenile males of highly social pelagic species may strand after being lost or displaced from bachelor schools; this is

Figure 1 *A sei whale* (Balaenoptera borealis) *stranded in Argentina in 1940. From Leatherwood* et al. *(1982).*

thought to happen to young Atlantic white-sided dolphins, *Lagenorhynchus acutus*, along the U.S. northeast coast during the fall. Some species follow the migrations of prey. Long-finned pilot whales, *Globicephala melas*, for example, pursue squid into shallow waters of Cape Cod Bay during the autumn and early winter and can be expected to strand at these times.

Mass strandings have always been the most puzzling. A large number of whales or dolphins of pelagic species such as sperm whales (*Physeter macrocephalus*), pilot whales (*Globicephala* spp.), false killer whales (*Pseudorca crassidens*), or Fraser's dolphins (*Lagenodelphis hosei*) may come ashore together for no apparent reason and in seeming good health (Fig. 2). While there undoubtedly is more than one cause of mass stranding in these animals, evidence is accumulating that caregiving behavior engendered by tight social bonds may be involved in at least some cases. For example, a herd of 30 false killer whales that semistranded in very shallow water in the Dry Tortugas in 1977 included a large male that was moribund due to illness or injury (Connor, 2000). The other whales clustered around this male and did not return to deep water until he died 3 days later. The whales became agitated when would-be rescuers tried to separate them and insisted on remaining in a tight group around the large male. Similar behavior has been reported for other mass strandings, with rescued individuals deliberately rejoining a group on the beach containing one or more severely ill or injured animals (Geraci *et al.*, 1999). In most cases, in the absence of human intervention, the entire group perishes, victims of a social cohesion that must be highly adaptive in other circumstances. On a population basis, mass stranding must be a rare event, or it could not persist evolutionarily. Suicidal mass stranding has been suggested as a possible mechanism for population regulation (Sergeant, 1982), but this smacks of the group selection hypothesis of Wynne-Edwards (1962), now largely discredited.

In some other instances of mass stranding, careful investigation has uncovered pathological evidence of widespread disease or parasitism that may have been causal or contributory. For example, about half of the mature females in a large stranded group of Atlantic white-sided dolphins were severely infected with a nematode to the extent that reproductive success was likely affected (Geraci *et al.*, 1978). In a stranding of 33 or more short-finned pilot whales, *Globicephala macrorhynchus*, in Florida, all live individuals examined were clinically ill, exhibiting an increased respiratory rate, difficulty in breathing, an elevated heart rate, and a wide range of metabolic and hematological abnormalities (Walsh *et al.*, 1991). As Walsh and colleagues noted: "In such a case, the actual etiology of the stranding event may be unknown because the original inciting factor, such as a virus, may have occurred days or even weeks before."

Figure 2 *A mass stranding of sperm whales in Oregon in 1979. Photo by Robert L. Pitman.*

Several additional causes for mass stranding have been posited (Geraci and Lounsbury, 1999). Areas with broad tidal flats, strong or unusual currents, or extreme tidal volume may lead to errors of navigation or judgment that result in stranding. It has been suggested that pelagic animals may run aground in shallow water because their echolocation is impaired. Others believe that cetaceans use the earth's magnetic field for navigation and are led astray by magnetic anomalies or disturbances. However, the only apparent common factor is strong social cohesion, strong enough that when a single animal comes ashore, for whatever reason, others in the group are likely to follow.

Mass strandings may be increasing in frequency, due possibly to anthropogenic causes. For example, during the period 1981 and 1991, there were 20 mass strandings of long-finned pilot whales, on 32 miles of beach in Cape Cod, Massachusetts, whereas only 1 had been reported in the previous 20 years, and epidemiological evidence suggests a possible link with recent morbillivirus outbreaks affecting a number of marine mammal species in the North Atlantic and Mediterranean (Geraci and Lounsbury, 1999; Duignan *et al.*, 1995). The impact of a viral outbreak may be potentiated by organochlorine pollutants that weaken the immune system.

II. What Can Be Learned from Strandings?

All we know about many species of cetaceans is only what we have learned from strandings. This is true for many of the BEAKED WHALES, the *Mesoplodon* species, for example. They are not kept in captivity for exhibit, are hunted only rarely and in remote parts of the world, and are relatively rare, elusive, and notoriously difficult to observe at sea. A rotting carcass on the beach can yield invaluable information on such things as anatomy, life history, genetics, disease, parasites, predators, contaminants, and feeding ecology. A live strandling transported to a holding facility can inform us about physiology, behavior, and cognition. A mass stranding offers a population sample (albeit potentially biased), opening to view parameters such as sex ratio, age structure, pregnancy rate, lactation rate, and relatedness within a group. Every stranding event should be considered a potentially unique opportunity to learn something that cannot be learned any other way.

III. Stranding Programs

In order to take full advantage of the scientific opportunities offered by stranded marine mammals, formal stranding response programs have started up in many parts of the world. One of the first was begun by Frederick True, the noted cetologist and one of the first curators of the U.S. National Museum of Natural History (Smithsonian Institution) in Washington, DC, and resulted in the beginnings of the largest collection of marine mammal specimens in the world. The stranding program has continued to the present (Fig. 3) and is a world model for stranding-response procedures and data and specimen collection and curation (Geraci and Lounsbury, 1993). Another early stranding program began in Britain when

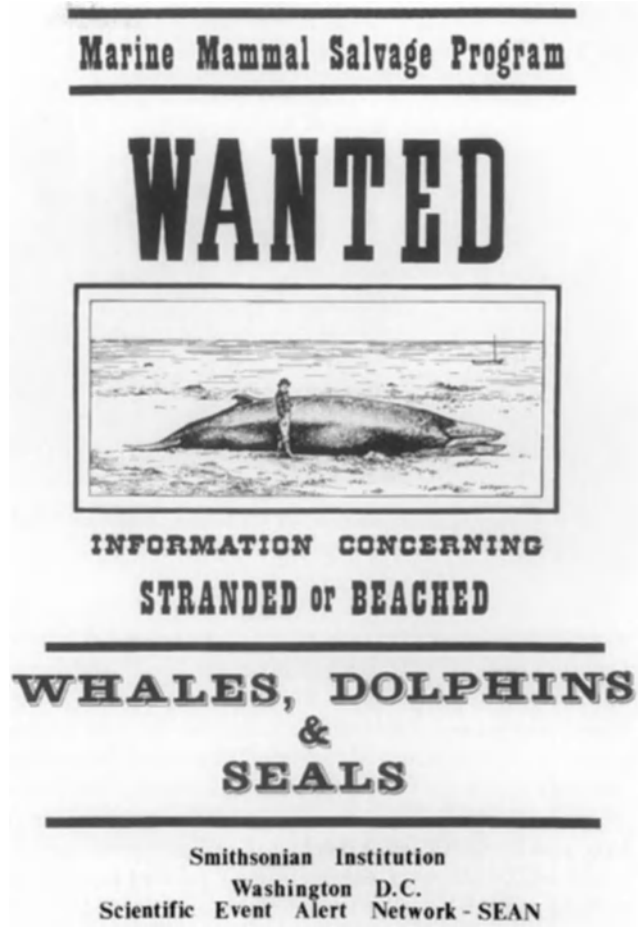

Figure 3 *Stranding poster issued by the Smithsonian Institution in the 1970s.*

the board of trade instructed receivers of wrecks to send telegraphic reports of the stranding of whales to the British Museum (Harmer, 1914). As "Royal Fishe," stranded cetaceans are property of the Crown and thus receive special attention and care. This has resulted in a long series of detailed data reports on Cetacea stranded on British coasts and basic knowledge of many North Atlantic species, as well as an immense and irreplaceable collection of specimens (Fraser, 1974; Sheldrick *et al.*, 1994). Perhaps the oldest stranding program, although not scientifically based or motivated, is in Vietnam, where cetaceans are revered as sea-going friends and souls, and those washing ashore have been collected and their skeletons preserved in Buddhist temples for centuries; these accumulations are now yielding information on the cetacean fauna of the region (Smith *et al.*, 1997).

In recent years, formal stranding programs have been established in many countries, including Australia, Japan, New Zealand, Canada, France, Italy, Argentina, Brazil, Thailand, the Philippines, and others. In the United States, a national stranding alert network and officially mandated regional stranding programs arose after passage of the Marine Mammal Protection Act in 1972. These new programs around the world are

motivated not only by scientific considerations, but by the desire to achieve humane treatment of live stranded animals, rescuing them if possible. The goals of these programs are well established (Geraci and Lounsbury, 1993): provide for the welfare of live animals, minimize risk to public health and safety, support scientific investigation, and advance public education.

IV. What Should Be Done with Live-Stranded Marine Mammals?

First, it must be recognized that marine mammals are under legal protection in many countries, and anyone who interferes with them, even though well-meaning, may be breaking the law. The first response should be to notify the relevant authorities so that if there is a formal stranding program in the area it can go into action. A telephone call to the nearest natural history MUSEUM, oceanarium, fisheries laboratory, or marine wildlife agency will help the information get to the right place.

Not every live animal on the beach needs help. Pinnipeds and sea otters spend time out of the water in the course of their normal affairs. Even some cetaceans may come into very shallow water or ashore for brief periods, e.g., a killer whale to snatch a seal or a bottlenose dolphin to ride a wave. However, certain conditions are unambiguous and do demand attention: a live dolphin obviously in distress on a beach, a sea otter coated with oil, a fur seal too feeble to move, or a porpoise trapped in a fishing weir. Although it is not always possible to judge the health of a cetacean by its outward appearance, coastal animals such as bottlenose dolphins, *Tursiops truncatus*, usually strand singly only when ill and likely will need rehabilitation to survive. Many pelagic cetaceans come ashore in apparent good health, or at least free of recognizable disease, and have a reasonable chance of withstanding the rigors of being returned to sea, although their long-term survival is undocumented.

Once a decision is made to do something about a live stranded animal, there are three options: return it to the sea, euthanize it, or transport it to a care facility (oceanarium or marine mammal rescue center) for rehabilitation (Fig. 4). The basic consideration should be to take no action that will only prolong suffering. The basic criteria for making a decision are (1) whether logistical support is available (e.g., a large dolphin or whale cannot be transported without a truck and means to put the animal on it), (2) the number of animals involved (a mass stranding may be a logistical nightmare), (3) the environmental conditions (rough seas, harsh terrain, darkness, or simply a rising tide can increase the risk to the animal and the team, or extremes of heat or cold may affect the animal's ability to thermoregulate), (4) condition of the animal(s) (a healthy animal is resilient, whereas one that is ailing may not survive the ordeal associated with a rescue), and (5) ease of handling (a very large or struggling animal may be impossible to rescue).

Immediate return to the sea is an option when the animal is manageable, healthy, and able to function normally; logistical and environmental conditions are favorable; social obligations (e.g., maternal care for the young) can be met; and the area of release is within the normal range of the animal, suitable and navigable. Single-stranded odontocetes, and sea otters or pinnipeds unable to leave the shore, are usually poor candidates for immediate release. Before an animal is released, a plan should be made for monitoring it after release.

Figure 4 *A stranded pygmy killer whale,* Feresa attenuata, *brought into the Miami Seaquarium. From Leatherwood* et al. *(1982).*

Rehabilitation is an option when there is a good chance the animal can be restored to health, facilities are available and equipped for the species and number of animals involved, arrangements can be made for safe and quick transport, the animal is manageable, and, very importantly, there are sufficient funds and staff to provide care for a reasonable period. It should be noted that even where care facilities are increasing in number, more animals come ashore than can be taken into the existing facilities.

Euthanasia is an option when it is necessary to end the suffering of an animal in irreversibly poor condition, no rehabilitation facility is available for orphaned dependent young, rescue is impossible and no care facility is available, animals persistently restrand, or a distressed cetacean ashore is likely to attract others milling nearby to mass strand. The procedure should be carried out humanely by an experienced qualified person and only if essential equipment and materials are available. A clumsy attempt to euthanize an animal without adequate equipment or expertise can cause more suffering than a natural death.

The time between discovery of a stranded cetacean and arrival of a stranding response team can be used by volunteers to relieve stress and improve the animal's chance of recovery. The key is to prevent further injury and keep the animal comfortable while minimizing handling and disturbance. The animal should be protected from blowing sand and kept moist with clean fresh or salt water. Care should be taken to keep water and sand out of the blowhole. In the summer, shade should be provided against the sun. If small, the animal can be positioned on its belly and holes dug to accommodate its flippers. The

animal should be out of the surf and protected against lacerations by sharp rocks and seashells.

Moving, release, tagging, transport, rehabilitation, or euthanasia should only be done by qualified, experienced personnel. Detailed guidelines are available in various manuals and government publications (e.g., Geraci and Lounsbury, 1993).

Mass strandings present a special challenge and can only be coped with effectively by an organized stranding response team backed up with adequate resources. One person, the stranding coordinator, must be in charge of all on-site activities. Volunteers are often indispensable, but their activities must be closely overseen by the coordinator. The goal should be the swift release of the largest manageable number of animals that have the best chance of surviving. Live animals should be dealt with first. The animals judged to have the greatest prospect of survival should be given priority, not those near death. The integrity of the group may be important to survival of the released animals. A proven approach is to relocate as many animals as possible to a safe place in shallow water where they can rest and become reoriented among their fellows. After tagging and monitoring of condition, the animals can be released together into open water. Because mass-stranded animals returned to sea may restrand, sometimes immediately but often days or even weeks later, released whales or dolphins should be monitored on a long-term basis, through direct observation (by cooperating fishermen, Coast Guard, sailing clubs, etc.) or telemetry.

V. What Should Be Collected from a Stranded Carcass?

The condition of a carcass determines much about what can be collected from it and should be specified in field notes. Standard condition codes are (1) alive, (2) freshly dead (i.e., edible), (3) decomposed, but organs basically intact, (4) advanced decomposition (i.e., organs not recognizable, carcass intact), and (5) mummified or skeletal remains only. The quality of information that can be obtained depends on a number of additional factors, including location; size, skills, organization, interests, and morale of the team; adherence to clear, detailed protocols; availability of equipment and supplies; number of animals to be examined; amount of time available; and care maintained in packaging, labeling, shipping, and storing samples. It is well recognized that it is not possible or practical to collect maximal samples and data in all cases; the effort must be tailored to the conditions. As a rough guide, three levels of collection have been described (modified slightly from Geraci and Lounsbury, 1993):

Level A Data: Basic Minimum Data

1. Name and institutional address of investigator.
2. Reporting source.
3. Species (including preliminary identification and voucher material in the form of photographs in several views, teeth, skulls, and other specimens).
4. Field number.
5. Number of animals, including total and subgroups.
6. Location (preliminary description, plus longitude and latitude and closest named cartographic feature).
7. Date and time of discovery and of specimen recovery.
8. Length (and girth and weight if possible).
9. Sex.

Level B Data: Supplementary On-Site Information and Samples

1. Weather and tide conditions.
2. Offshore human/predator activity.
3. Presence of prey species.
4. Behavior before and during stranding.
5. Samples collected for life history studies (teeth, earplugs, or bone for age determination, reproductive tracts, stomachs).
6. Samples collected for blood studies.
7. Samples collected for genetic studies.
8. External measurements.
9. Disposition of carcass.

Level C Data: Necropsy Examination and Parasite Collection

1. Collection of tissues for toxicology, microbiology, and gross histopathology.
2. Collection of parasites.

Detailed protocols for collection of data and specimens are contained in stranding and dissection manuals (e.g., Geraci and Lounsbury, 1993; Jefferson *et al.*, 1994). It must be stressed that information has scientific value only when documented carefully. In the case of a mass stranding, it is better, after collecting the minimal basic data for all, to obtain good samples and perform thorough examinations with accurate documentation on a small number of animals than to do a hasty job on many.

Streamlining

Frank E. Fish
West Chester University, Pennsylvania

Streamlining has a major impact on the ecological performance of marine mammals. Because swimming is an integral behavior of marine mammals that forage, mate, escape predation, disperse, and migrate in water, constraints on performance promoted adaptations for effective locomotion by aquatic mammals. To propel itself through the water at a constant swimming speed, a marine mammal needs to generate a forward force (thrust) at the expense of metabolic energy that is equal and opposite to the sum of resistive forces (drag).

I. Drag

Two major types of drag are experienced by a marine mammal as it swims submerged. These include the pressure or form drag and the viscous or skin friction drag. The pressure drag results from the pressure distribution around the body. As water flows about a body, a high pressure is generated at the upstream face and a lower pressure is generated at the downstream face. This difference in pressure produces a force, pressure drag, which opposes forward movement. Viscous drag is a function of the viscosity or stickiness of the water around the body. Water particles adhere to the body surface within a thin layer of water adjacent to the body, called the boundary layer. Friction within the boundary layer and between the boundary layer and the body create a force in the drag direction. The magnitude of the viscous drag will depend on the wetted surface area of the body and the flow conditions within the boundary layer. Boundary flow can be laminar, turbulent, or transitional. A boundary layer with turbulent flow produces the highest viscous drag.

Drag is minimized primarily by streamlining the shape of the body and the appendages. The streamlined profile of these structures has a fusiform design resembling an elongate teardrop with a rounded leading edge extending to a maximum thickness and a slowly tapering tail. This shape was first investigated in the dolphin by Sir George Cayley (circa 1800) as a solid of least resistance design (Fig. 1). As shown in Fig. 2, marine mammals display a streamlined, fusiform design. This fusiform shape is sculpted by the distribution of blubber and/or fur covering the body. Modern submarines utilize a fusiform design analogous to the body shape of marine mammals. In addition, the appendages, such as the flukes, flippers, and dorsal fin, have a cross-sectional shape similar to conventional aircraft wings and hydrofoils.

Streamlining minimizes drag by reducing the magnitude of the pressure difference over the body. This reduced pressure difference allows water in the boundary layer to flow without separation from the body surface until near the trailing edge. As separation occurs, a wake is generated downstream. The wake behind the body is small, indicating little distortion to the flow and a small pressure drag. Premature separation of the boundary layer occurs because of instabilities in the flow. A laminar boundary flow is inherently less stable and more prone to premature separation than turbulent flow. An animal may pay a higher energetic cost in frictional drag by allowing the development of a turbulent boundary layer, but the pressure and total drags will be substantially lower than if laminar flow with separation transpires.

II. Body Shape

An indicator of the degree of streamlining is the fineness ratio (*FR* = body length/maximum diameter). The *FR* value of 4.5 gives the least drag and surface area for the maximum volume, although only a 10% increase in drag is realized in the *FR* range of 3–7 (Fig. 3). Marine mammals are well streamlined with body dimensions within the optimal range of *FR*. In general, cetaceans, pinnipeds, and sirenians have body shapes with *FR* between 3.3 and 8.0 (Fig. 3). The notable exception for cetaceans is the northern right whale dolphin (*Lissodelphis borealis*) or "snake porpoise" that can have a *FR* up to 10.9. Despite their bulk and specialization of the head for filter feeding, mysticete whales are well streamlined. *FR* for Balaenopteridae ranges from 4.8 to 8.1 and for Balaenidae ranges from 3.3 to 8.0.

FR is, however, a crude indicator of the streamlining of the body because it does not provide information on changes in

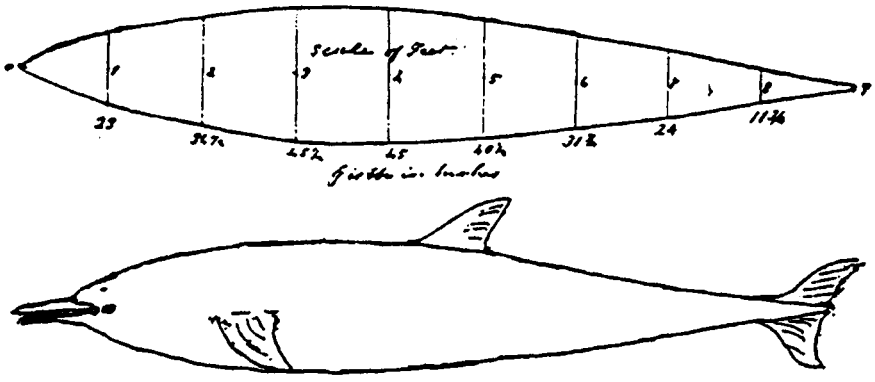

Figure 1 *Sketch of dolphin and body contours by Sir George Cayley (ca. 1800).*

body contour. Another indicator of body streamlining is the position of the maximum thickness, called the shoulder. Shoulder position is important because this is where transition from laminar to turbulent flow and boundary layer separation are likely to occur. Anterior of the shoulder the pressure distribution favors maintenance of a laminar boundary layer. The position of the shoulder in the most rapidly swimming aquatic mammals is displaced posteriorly, which is similar to engineered wings with "laminar" profiles, which reduce drag through maintenance of laminar boundary flow. The shoulder position for dolphins is 34–45% of the body length from the beak.

The shoulder position is located at 40% of body length for otariid seals and 50–60% of body length for phocid seals from the nose. The position can be varied in pinnipeds because the neck is capable of being retracted and extended. Extension of the neck during rapid swimming could modify the flow over the anterior of the seal and reduce drag by extending the region of laminar flow. Such a drag reduction could aid seals in catching fast-swimming, elusive prey.

Experiments on flow visualization using a fluorescent dye applied to a dolphin's melon showed the flow to be laminar over the anterior 32% of the dolphin. Transition began before the dorsal fin with turbulence aft of the fin. Separation of the boundary flow occurred smoothly near the base of the flukes. Flow visualization using BIOLUMINESCENCE within the boundary layer of dolphins and seals similarly indicated a lack of separation from the body surface. Flow separation is restricted to the tips of the flukes, flippers, and dorsal fin. The flow separation has been observed as bioluminescent "contrails" (Fig. 4).

The contrails are vortices generated at the tips of the appendages. A tip vortex is generated from pressure differences along the two surfaces of the appendage. The pressure difference produces a lift force similar to the lift produced by airplane wings. Marine mammals utilize lift generated from the appendages to propel the body, increase stability, regulate depth, and maneuver. A consequence of the tip vortices is the loss of energy from the generation of lift, which is referred to as an induced drag.

The induced drag and interference to the flow over the body due to the addition of the appendages can interfere with streamlining. The dorsal fin, pectoral flippers, and flukes comprised only 2.6, 4.2, and 5.6% of the total surface area of the harbor porpoise (*Phocoena phocoena*), respectively; however, these appendages are responsible for 35.7% of the total drag (4.3, 18.0, and 13.4%, respectively). Induced drag is reduced by appendages with a long narrow shape and tips that taper sharply to a point (Fig. 5).

Streamlining is also fostered through buoyancy control. Compared to the center of gravity, the center of buoyancy is closer to the head for terrestrial mammals in water. This relationship produces a torque that causes the body to float at an angle to the horizontal. This orientation would decrease streamlining. Internal and external modifications for buoyancy control provide aquatic mammals with longitudinal trim for better streamlining by presenting a smaller body area to the oncoming flow. For sea otters, nonwettable fur provides buoyancy by an entrapped layer of air to maintain a horizontal body orientation when swimming at the surface. The elongate shape of the lungs of marine mammals helps displace the center of buoyancy posteriorly. This arrangement is possible because the diaphragm of marine mammals is oriented obliquely to almost parallel to the spine.

III. Drag Reduction Mechanisms

High swimming speeds attained by many marine mammals have directed some research toward specialized drag reduction mechanisms. In what is known as Gray's paradox, hydrodynamic estimates of dolphin power output at high speeds were inferred to be greater than the power that could be developed for the mass of muscle available for swimming. Resolution of the paradox was believed only possible if the drag was reduced by maintaining laminar flow within the boundary layer, despite a high swimming speed dictating a turbulent boundary flow with increased viscous drag.

While the idea of a special drag reduction mechanism in dolphins has been irresistible, direct evidence of its existence has been elusive. To date, no conclusive evidence has been found of laminar boundary flow over the entire body surface of fast swimming dolphins by mechanisms including compliant skin dampening, secretions, skin cell sloughing, infusion of long-chain polymers into the boundary layer, boundary-layer heating, skin folds, and boundary layer acceleration. Special drag reduction mechanisms are unnecessary to explain Gray's paradox, which is reconciled when one considers that the calculations of power output were based on burst swimming (10

Silhouettes show the difference in shape in reference to* FR *from a circular shape* (FR = *1) to an elongate form* (FR = *7).*

m/sec for 7 sec) and that muscle power output was an underestimate based on sustained performance of dogs and humans.

The naked skin of cetaceans is regarded as a means to maintain a smooth flow with an attached boundary layer over the surface of the body. In addition, cells of the epidermis are produced rapidly, which promotes a high rate of skin sloughing. This increased skin sloughing deters organisms, such as barnacles, from attaching to the skin and thus minimizes drag. The properties of the hair of aquatic mammals are noted to reduce drag by aiding in streamlining of the body. The lack of erector pili muscles in seals and sea otters permits the pelage to lie flat in water, minimizing resistance to swimming.

Behavioral mechanisms are also used to minimize drag. Porpoising, which is performed by the fastest swimmers, is a series of rhythmic leaps. By traveling through the air for a given distance, the animal reduces its drag compared to swimming over an equivalent distance underwater. This reduction in drag is due to the lower density and viscosity of air compared to water. In addition, swimming near the water surface to facilitate breathing incurs a large drag increment due to the energy lost for the animal in the formation of surface waves. Porpoising becomes economical only at high swimming speeds when the cost of LEAPING from the water becomes smaller than the drag on the animal in water. In addition, porpoising is associated with the need to increase ventilation time resulting from greater ENERGETIC demands of rapid swimming.

Many dolphins utilize free-riding behaviors to reduce the energy cost of swimming. In this behavior, the dolphin takes advantage of the pressure field generated by another body and moves along with little or no energetic input. Dolphins have been observed to ride the pressure waves of ships and large whales. By situating itself on the bow wave, the small cetacean can be pushed along or surf down the front slope of the wave. This latter mechanism is analogous to human surfing. Sea lions will surf on breakers to get up onto beaches.

Formation swimming influences the water flow around adjacent individuals. Drafting is the beneficial use of the water flow to

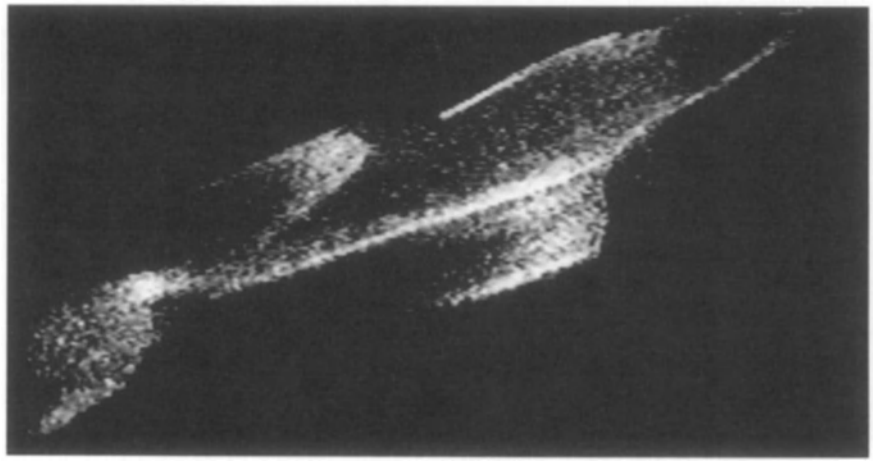

Figure 4 *Bioluminescent image of a gliding dolphin* (Tursiops truncatus) *showing lack of separation from the body surface. Photograph courtesy of Jim Rohr, Michael Latz, and Mark Stevenson.*

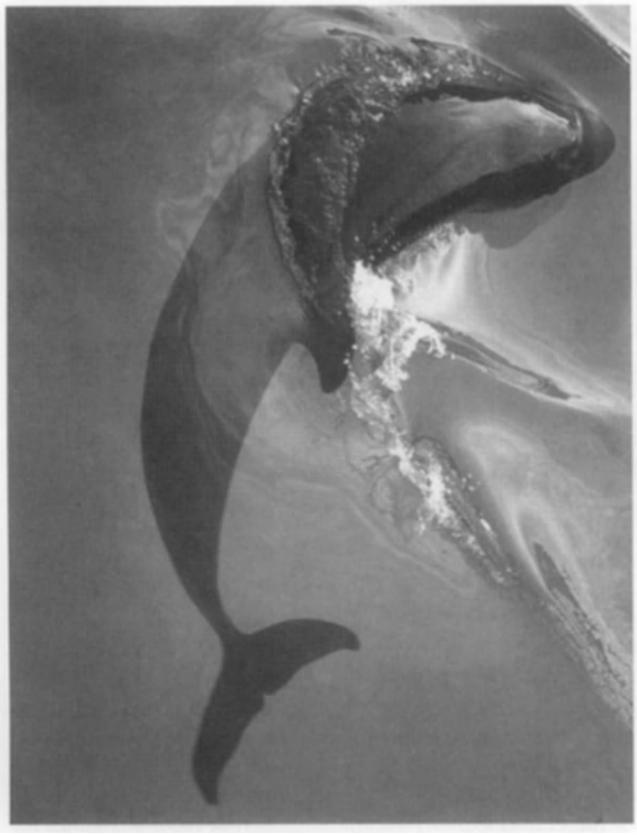

Figure 5 *False killer whale* (Pseudorca crassidens) *displaying highly tapered and elongate appendages.*

reduce drag with a concomitant decrease in the energy cost of locomotion. Large groups of dolphins will organize into side-by-side and echelon formations. Drafting becomes particularly important to young whales to maintain speed with their mothers. A calf swims next to the maximum diameter or near the genital region of the mother. At these locations, the calf is in a hydrodynamically favorable position arising from the interaction of its pressure field with that of the mother's. The calf experiences a thrust component pulling it along with the mother, who experiences increased drag.

Striped Dolphin

Stenella coeruleoalba

Frederick I. Archer II

Southwest Fisheries Science Center, La Jolla, California

The striped dolphin, *Stenella coeruleoalba* (Meyen, 1833) is a pelagic small delphinid common in warm-temperate to tropical waters around the world. The trivial name, *coeruleoalba*, refers to the diagnostic pattern of blue and white stripes and blazes along the lateral and dorsal sides of their bodies. These dolphins have been well studied in several regions where they occur, such as the western North Pacific, eastern tropical Pacific, and the Mediterranean. They are known to be social and very acrobatic, but at least in the eastern tropical Pacific, wary of boats and do not bow ride.

I. Characters and Taxonomic Relationships

The most striking characteristic of striped dolphins is their bold blue and white color pattern (Fig. 1). The primary features are an eye-to-anus and an eye-to-flipper stripe that are dark blue or bluish black. The dorsal cape is a muted blue or bluish-gray, usually invaded by a white to light gray spinal blaze that flows from the lateral field. The lateral field is usually darker than the ventral field. A dark stripe bifurcating from the eye-to-anus stripe and continuing into the ventral field is usually present. A faint secondary stripe may also be present in the ventral field.

Striped dolphins are similar to most other small oceanic dolphins, having a long beak (well demarcated from the melon) and falcate dorsal fin. In the field they are most likely to be confused with common dolphins (*Delphinus delphis* and *D. capensis*) Fraser's dolphin (*Lagenodelphis hosei*), spinner dolphins (*S. longirostris*), or Clymene dolphins (*S. clymene*) but can be easily distinguished by their robust body and coloration. The longest recorded specimen was 2.56 m and the heaviest specimen weighed 156 kg. Mean maximum body length in the western Pacific is 2.4 m for males and 2.2 m for females (Archer and Perrin, 1999).

Variation in skull and body size has been documented among several geographical regions and there is evidence that further population subdivision may occur within some of these regions. Cranially, *S. coeruleoalba* most closely resembles *S. clymene*, but

Figure 1 *A striped dolphin,* Stenella coeruleoalba.

is significantly larger (Perrin *et al.*, 1981). Sequence analysis of the cytochrome *b* mitochondrial gene supports a sister species relationship between these two species. The two share an unresolved polytomic clade with *Delphinus* spp., *S. frontalis* and *Tursiops aduncus* (LeDuc *et al.*, 1999). However, as the genus *Stenella* was found to be paraphyletic in this study, the final taxonomic resolution of striped dolphins awaits further work.

II. Distribution and Ecology

The range of striped dolphins is well documented in the western and eastern North and tropical Pacific, where most records are below about 43°N. The species has been recorded from the Atlantic coast of northern South America up to the eastern seaboard of North America, with the northern limit a function of the meanderings of the Gulf Stream. *S. coeruleoalba* is found in the eastern North Atlantic south of the United Kingdom and is the most frequently occurring dolphin in the Mediterranean Sea. It has also been documented from the coast of several countries bordering the Indian Ocean, but its full range in this region is unknown. Striped dolphins can usually be found outside the continental shelf, typically over the continental slope out to oceanic waters, often associated with convergence zones and waters influenced by upwelling. The species has been reported in waters of 10 to 26°C, although most records are from about 18–22°C (Archer and Perrin, 1999).

Striped dolphins feed on a variety of pelagic or benthopelagic fish and squid. Off the coast of Japan and South Africa, fish in the family Myctophidae are the dominant prey items, while they primarily feed on cod in the Northeast Atlantic and prey on squid more in the Mediterranean (Perrin *et al.*, 1994). To reach potential prey, striped dolphins may be diving from 200 to 700 m. Attacks by both sharks and killer whales (*Orcinus orca*) have been reported for this species (Archer and Perrin, 1999).

As a result of a large number of specimens available from the Japanese drive fishery and a morbillivirus epizootic in the western Mediterranean, contaminants and PARASITES have been studied more intensively in this species than in any other cetacean. High organochlorine loads in the western Mediterranean population have been hypothesized to have caused an immunodepressive state, thus decreasing resistance to infection, which in turn led to the deaths of thousands of dolphins from 1990 to 1992. Blubber PCB levels from animals affected by the epizootic may be among the highest recorded values for any mammal (Archer and Perrin, 1999).

III. Behavior and Life History

Striped dolphins perform a variety of aerial behaviors, such as breaching, chin slaps, and a unique behavior termed "rototailing," in which they make high arcing jumps while rapidly rotating their tail before reentering the water. School sizes vary between regions, ranging from 10–30 to several hundred individuals, but rarely greater than 500 (Archer and Perrin, 1999). In the western Pacific, a complex schooling system has been documented in which individuals move among juvenile, adult, and mixed schools (Miyazaki and Nishiwaki, 1978). The adult and mixed schools are further divided into breeding and nonbreeding schools in what is likely to be a polygynous mating system.

MATING is seasonal, with gestation lasting from 12 to 13 months. Body length at birth has been estimated to be between 93 and 100 cm. Males enter sexual maturity between 7 and 15 years of age, whereas females become sexually mature between 5 and 13 years old. Mean length at sexual maturity is 2.1–2.2 m. Density-dependent changes in several life history parameters have been reported for the western Pacific population, probably as a result of large fishery kills. Maximum estimated age for both males and females is 57.5 years (Archer and Perrin, 1999).

IV. Interactions with Humans

The western North Pacific population of striped dolphins has experienced its heaviest mortalities from Japanese striped dolphin drive and hand-harpoon fisheries. Annual catches in one re-

gion during the 1940s and 1950s were ca. 8000–9000 animals, reaching as high as 21,000 in some years. However, self-imposed quotas, lower encounter rates, and the dissolution of a fishery cooperative caused annual catches to drop to below ca. 1000 in the early to mid-1980s (Kishiro and Kasuya, 1993). Other directed takes of the species have occurred in St. Vincent and the Mediterranean for human consumption and protection of fishing gear. INCIDENTAL CATCHES have also been recorded from various gear in fisheries across their range. Striped dolphins have not been successfully maintained in captivity, where most have died within 1–2 weeks after not feeding well (Archer and Perrin, 1999).

Surveys

KARIN A. FORNEY
Southwest Fisheries Science Center, La Jolla, California

Surveys are used to address many different marine mammal research questions, including distribution, abundance, trends, and habitat associations. Equipment and methodology vary depending on the species of interest, financial resources, availability of research platforms, and survey objective. Marine mammals at sea are most commonly surveyed aboard ships or large boats or from fixed-wing aircraft. Small boats, helicopters, airships, and land-based viewing stations are also used when appropriate. Line-transect methods are often the most effective for estimating the abundance of marine mammals at sea, although other survey techniques are also used. Marine mammals on or near land, such as pinnipeds, sea otters, or walruses, are more commonly counted from land-based viewing points or using aerial photography.

Figure 1 *NOAA ship* McArthur, *which has been used for many marine mammal surveys in the eastern Pacific Ocean. Photograph by Karin Forney.*

I. Vessel Surveys

Large oceanographic research vessels (Fig. 1) are the most versatile platform for at-sea surveys of marine mammals. They can carry a dozen or more researchers and remain at sea for weeks at a time, providing the ability to cover extensive marine areas. Search efficiency is greatest aboard these large vessels because observers can search from a greater height above the water (on the flying bridge, bridge, or in a crow's nest) and use high-power, deck-mounted binoculars ("big eyes"; Fig. 2) when searching for and identifying marine mammals. Large research vessels usually also have equipment for collecting oceanographic data for marine mammal habitat studies and may be able to tow hydrophones to detect marine mammals acoustically. A

Figure 2 *"Big eyes" used to search for marine mammals on large survey vessels. Photograph by Jay Barlow.*

Figure 3 *Small survey vessel used in the Philippines. Photograph by Louella Dolar.*

significant disadvantage to large research vessels, however, is their great operating cost: approximately $10,000 per day. Small or medium-sized vessels (Fig. 3), including a variety of fishing boats and sail boats, have been used successfully for surveys at a significantly reduced cost. This is the most feasible option in many parts of the world, particularly in developing countries. On these smaller vessels, searching is usually conducted with hand-held binoculars or by naked eye from the highest stable deck or platform on the ship. In some shallow bays and rivers, even smaller boats (e.g., rigid-hull inflatable boats, Boston Whalers) may be required for safe navigation. Auxiliary studies, including photography, biopsy sampling, diving behavior, and prey sampling, are also often possible during vessel surveys.

II. Aircraft Surveys

The main advantages of aerial surveys are the ability to cover large areas quickly and the lower cost of aircraft compared to large ships. They are most useful for preliminary studies to determine the relative distribution and presence or absence of species in a particular region but can also be used to estimate abundance and monitor trends. Aircraft with high wings and bubble windows (Fig. 4) are best-suited because they allow lateral viewing as well as some downward visibility. An additional downward-viewing ("belly") window enhances sighting efficiency considerably because marine mammals are seen most easily from the air when viewing perpendicular to the water surface. A typical aerial survey observer team consists

Figure 4 *NOAA Twin Otter survey aircraft with bubble window (under propeller) and belly window part (above tire). Photograph by Karin Forney.*

of two observers searching through the two side windows, one data recorder, and, if possible, a belly observer.

III. Land-Based Surveys

A few populations of whales reliably migrate close to shore and have been surveyed successfully from land-based stations. These include bowhead whales at Point Barrow, Alaska, and gray whales along the California coast. During these surveys, visual and acoustic means may be used to record all whales that travel past the observation point during the migratory period. Adjustments are made for unobservable periods, such as nighttime and times of poor weather conditions. Pinnipeds are counted most commonly from land-based viewing stations, such as cliff tops, although aerial photographs can provide an excellent alternative means of surveying these animals along the coastline.

IV. Methodological Considerations

Detectability of marine mammals is a key factor in deciding what type of survey platform to use. Animals that dive for prolonged periods, such as SPERM WHALES and BEAKED WHALES, will be missed much more frequently during aerial surveys than from ships because the aircraft travels much faster. For some species, correction factors have been developed to correct for the proportion of animals missed from airplanes or ships. Vessel attraction or avoidance is another concern when designing shipboard marine mammal surveys. For example, harbor porpoises are known to avoid vessels, and if animals are not detected before they react, resulting abundance estimates may be too low. The opposite problem exists for species that are attracted to vessels to "ride the bow"; in these cases abundance estimates may be too high. Both of these problems can be minimized by using a larger vessel that allows viewing from a greater height and with high-power binoculars; animals can then be detected at a greater distance before they react to the vessel.

Sustainability

CHARLES W. FOWLER
National Marine Mammal Laboratory, Seattle, Washington

Sustainability has been elusive. Sustainability is important in managing our use of resources (e.g., the harvest of both marine mammals and finfishes). Harvest levels must be established in ways that account for complexity, including the direct effects on harvested populations and such indirect factors as exemplified by the interactions between marine mammals and fish populations. The "sustainable development" of marine mammals is an unlikely option, partly because of their low productivity levels (e.g., Perrin, 1999). However, defining sustainability whether applied to marine mammals, fisheries, or ecosystems remains an important objective.

Historically, the concept of maximum sustainable yield (MSY) has played a major role in the management of our utilization of natural resources. This approach has yet to be assessed in its contribution to worldwide problems such as overharvested fish populations (e.g., Rosenberg *et al.*, 1993; Committee on Ecosystem Management for Sustainable Marine Fisheries, 1999). Commercial whaling and sealing have also involved concepts derived from the MSY approach.

The inadequacies of management based on MSY have been recognized and other methodologies have been developed

[e.g., the catch limit algorithm of the INTERNATIONAL WHALING COMMISSION (Slooten, 1996) and the potential biological removal approach (PBR) being used by the National Marine Fisheries Service in the United States (Wade, 1998)]. These alternatives, however, have not escaped the weaknesses of being applicable only to individual species and do not account for complexity. The ecosystem effects of fishing (e.g., Hall, 1999), whaling, or sealing are not adequately considered in current management strategies. The challenges currently facing management are not being met.

It is therefore extremely important to find alternatives that will work. One approach is systemic management (Fowler and Perez, 1999) in which empirical examples are used to define and measure sustainability. Along with other species, marine mammals are sources of information about sustainability that is broadly applicable and meets the demands being made of management.

Marine mammals serve as empirical examples of how sustainable roles, or niches, can be maintained in marine ecosystems because they have persisted as parts of such systems over evolutionary time scales. Resource consumption is a good example of a measure for describing sustainability. Both marine mammals and fisheries consume biomass from various resource species (e.g., fish or squid), making part of their interaction competitive. The various rates at which marine mammals consume biomass exemplify differing levels of sustainability. Importantly, there are limits to variation in such consumption rates. It is now being suggested that conventional approaches to management be replaced by a process that mimics empirical examples of sustainability (systemic management: Fowler *et al.*, 1999; Fowler and Perez, 1999). For example, such management would be carried out to ensure that fishery catches would fall within the normal limits of natural variation for consumption rates among other consumer species. Thus, observed examples of sustainable consumption rates can be used to regulate the catches taken by fisheries while simultaneously conserving resources and habitat for other species. As such, marine mammals, as well as other species, are empirical examples of sustainability that provide information that applies systemically.

I. Management Questions, Empirical Answers

How many tons of whales, seals, fish, cephalopods, or other resources should we harvest each year? What is the appropriate or optimal rate at which to harvest biomass, and when and where should it be harvested? Such questions can be asked with regard to a single resource species or with respect to any area of the oceans, an ecosystem, a group of resource species, a season, or the biosphere. How do we answer all such questions so that the answer for one case will not be in conflict with the answer for another? Empirical information is key to answering such questions consistently, and marine mammals are key elements in providing such information (Fowler, 1999; Fowler *et al.*, 1999).

Figure 1 shows frequency distributions (empirical probability distributions) for consumption rates exhibited by various marine mammals. Also shown, for comparison in each case, is the harvest rate for fisheries: the rate at which humans consume biomass. The top panel illustrates consumption from a population of an individual species, and the bottom panel represents total consumption within the biosphere. Intermediate panels depict consumption from a group of resource species, an ecosystem, and the marine environment. Thus, Fig. 1 represents information for a telescoped series of increasing complexity. In this case, the biosphere contains the marine environment, which, in turn, includes the ecosystem (Bering Sea). Within the ecosystem we find populations of resource species (the finfish), among which is the population of walleye pollock (*Theragra chalcogramma*, one species).

Various requirements are placed on management. It has been made clear that management should promote actions whereby components and processes within systems will fall within their normal range of natural variation (e.g., Christensen *et al.*, 1996; Mangel *et al.*, 1996). These include the components and processes that constitute individuals, species, ecosystems, and the biosphere. Humans (through commercial fishing) are obvious outliers relative to the natural variation illustrated in Fig. 1.

There are things management cannot do. The other species within these distributions are largely beyond our control, especially the collective aggregate of species in each distribution. Individual species can show change opposite to our intentions if we act to influence them directly. In fact, changes we stimulate in these species may result in unwanted reactions in the rest of the system whether we purposely manipulate them individually or as a group.

Management can move forward, however, by focusing on reducing consumption by humans to fall within the normal range of the variation exhibited by other species. Nonhuman species exhibit consumption rates that occur within the context of complexity—all the things that influence these species. That is, all the things that have contributed to the observed rates of consumption, such as those shown in Fig. 1, are taken into account.

Figure 1, then, is a rudimentary guide for the management of our use of fishery resources when achieving sustainability is the ultimate goal. Empirical data exemplify what works in the face of the complete suite of factors that set limits in the consumption of resources. Better options are found among the more numerous examples toward the centers of the distributions compared to the scarcity of examples in the tails (Fig. 1). The risks and constraints that prevent the accumulation of species in such regions are to be avoided. How, then, can we carry out sustainable management?

II. Management to Achieve Sustainability

It has long been recognized that we need a form of management that applies to ecosystems (Christensen *et al.*, 1996). To develop sustainable management strategies, humans must manage by consuming biomass from ecosystems at rates that are sustainable. Sustainable management requires change. For example, reducing consumption by humans to 10% of current harvest rates would place our species squarely within the normal range of natural variation shown in the ecosystem (third)

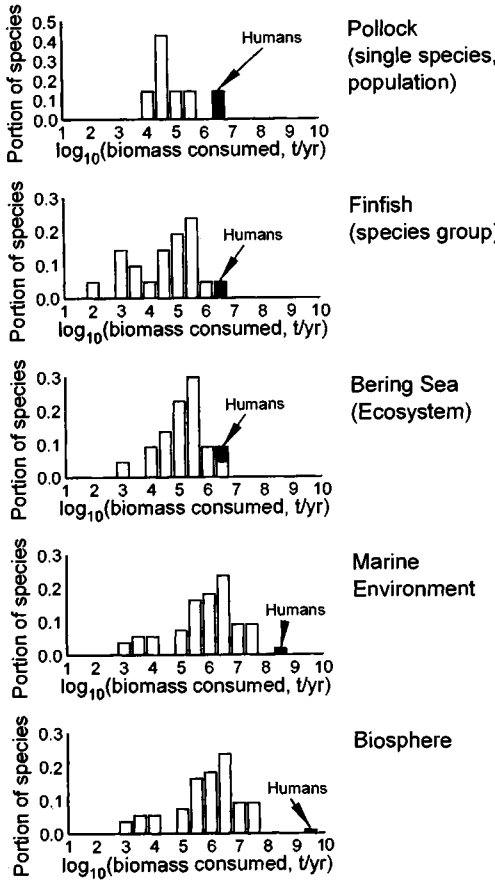

Figure 1 *The frequency distribution of consumption rates (tons of biomass consumed per year, in $\log_{10}$ scale) for marine mammals showing optimal consumption rates where most species are concentrated. The rate at which humans harvest biomass is shown for comparison. The top panel shows the natural variation in consumption of walleye pollock* (Theragra chalcogramma) *as observed for 6 species of marine mammals in the Bering Sea in comparison to recent takes of pollock by commercial fisheries (Livingston, 1993). The second panel shows consumption of finfish in the Bering Sea by 20 species of marine mammals compared to fisheries takes (predominantly pollock; Fowler and Perez, 1999). Total biomass consumption is shown for 20 species of marine mammals in the Bering Sea in the third panel, again compared to the commercial take, which is predominantly pollock (Fowler and Perez, 1999). Total biomass consumption for the entire marine environment (all oceans combined) is shown in the fourth panel for 55 species of marine mammals, here compared to the take of about 110 million metric tons estimated as the harvest of biomass for human use in the late 1990s (Committee on Ecosystem Management for Sustainable Marine Fisheries, 1999). Worldwide consumption of biomass by humans is compared to that of 55 species of marine mammals in the bottom panel. The last two panels are based on indirect estimates (Fowler and Perez, 1999) using population and body size data from the marine mammal series by Ridgway and Harrison (1981–1999) and equations representing ingestion rates as a function of body size in Peters (1983).*

panel of Fig. 1. Such change will require time to accomplish. Maintenance of reduced levels, once achieved, would lead to further challenges for management. These would include responding to changes within ecosystems over seasons, with shifts in climate, or in response to our management.

It has been recognized for some time, in the world of commercial fisheries management, that the historical focus on managing harvests from the individual-species point of view has been insufficient, partly because of the need to consider ecosystems. However, management restricted to ecosystems would be similarly insufficient because of the need to account for both the broader marine environment and the biosphere, as well as individual species.

Management based on empirical examples is an integrated approach that simultaneously helps define sustainable harvests at the level of individual species and the biosphere. For example, reducing harvests to between 1 and 10% of recent harvest levels would be required for the species represented in the top panel of Fig. 1. We can similarly account for multispecies groups and the entire marine environment (second and fourth panels, respectively, Fig. 1). The biosphere can be involved by reducing human consumption to about 0.1% of current consumption levels (Fig. 1, panel 5).

In all cases shown in Fig. 1, management would involve change measured in orders of magnitude to fall within the normal ranges of natural variation. If the distributions themselves change in response to the reduction of harvested biomass by humans, then sustainable management would need to respond to the new information. This requires continuous monitoring through concerted scientific effort to observe such changes.

III. Accounting for Complexity

In management, the list of things to be considered seems endless. For example, we need to account for the effects of evolution, we need to account for endangered species, and we need to deal with multiple complex processes, such as nutrient flow within ecosystems. It is often said that management needs to be interdisciplinary, or an integrated accounting of everything science can study. However, we also need to account for the things we do not, or cannot, study or know about. This is accomplished in two ways when we take advantage of empirical examples provided by species such as marine mammals.

First, every species reflects the effects of everything that influences it. These factors are integrated in the distributions shown in Fig. 1. For example, evolution is taken into account through its influence on the position of every species within each distribution. Each species represents a composite of balances among various opposing forces (e.g., those involved in predation, population growth, evolution, or extinction). Each species reflects the constraints of the system—constraints such as competition for the limited availability of energy in its path through the various trophic levels. The relative importance of each factor compared to every other factor is taken into account implicitly.

Second, we must expand our management questions. We must address the consumption of biomass in space and time. Distributions similar to those of Fig. 1 can be developed for the

allocation of biomass consumption over alternative resource species, seasons, and geographic space. We have to deal with complexity by addressing the other management questions before us. Marine mammals can be used as empirical examples in such an endeavor, and through such species we account for the unknowns that influence the position of each species in distributions similar to those of Fig. 1. For marine mammals themselves, finding the rates at which they can be harvested sustainably would involve information regarding consumption by their predators, including other marine mammals!

IV. Consistency

An important aspect of empirical examples is their representation of a system that is internally consistent. Advice for management at the ecosystem level (Fig. 1, panel 3) will be consistent with advice at the individual species level (panel 1) when applied simultaneously. Collective application at the individual species level must be constrained to the limits set by application at the ecosystem level. Nutrients, energy, biomass, and species involved in this systemic consistency guarantee freedom of conflict because the conflicting forces of nature result in what we see in distributions derived empirically.

Marine mammals can serve as empirical sources of information about how SPECIES fit into ecosystems. Through information about other species, such as marine mammals, we are provided with guidance about sustainable harvest levels (e.g., total biomass consumed per year), allocation of harvests over time and space, allocation across resource species, and other management questions.

Susu and Bhulan

Platanista gangetica gangetica and *P. g. minor*

BRIAN D. SMITH
Aquatic Biodiversity Associates, Eureka, California

The susu and bhulan, *Platanista gangetica gangetica* and *P. g. minor*, are two river dolphins of the South Asian subcontinent. Some scientists dispute the existence of one species and consider them to be separate, *P. gangetica* and *P. minor* (Pilleri *et al.*, 1982). A variety of vernacular names are used for the susu and bhulan, mostly connoting the sound made during respiration. For the susu, these include *swongsu* and *sus matsya* (*matsya* = fish) in Nepali, *soonse* and *sunsar* in Hindi, *hiho* and *shihu* in Assamese, and *shushuk* and *sishu-, foo-*, or *hungmaach* (*maach* = fish) in Bengali. For the bhulan, these include *bhoolun* and *sisar*.

I. External Appearance

The subspecies are nearly identical in external appearance (Fig. 1). Their body is supple and robust, attenuating behind

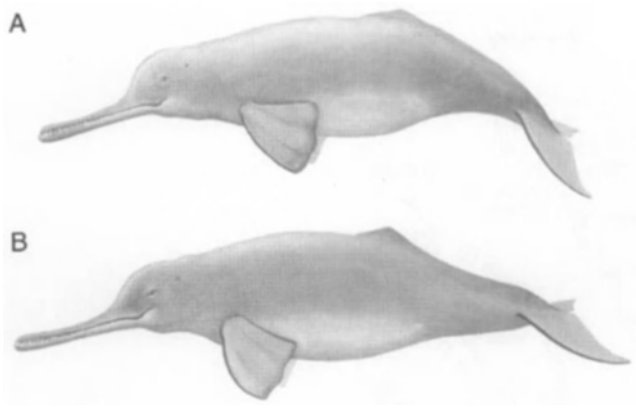

Figure 1 *(A) The susu* (Platanista gangetica gangetica) *and (B) bhulan* (P. g. minor) *are river dolphins with long narrow snouts reminiscent of gharial crocodilians* (Gavialis gangeticus) *that are also found in some of the same rivers. These endangered taxa were once hunted, a practice now prohibited. Entanglement in gillnets, water development, pollution, and occasional poaching are adversely affecting the survival of this species. Pieter A. Folkens/Higher Porpoise DG.*

the dorsal fin in a narrow tail stock. COLORATION is gray overall, becoming blotchy with age. Bellies of young animals are lighter and often have a pinkish hue. The dolphins have a long snout that becomes wider at the tip. Adult females generally have a longer snout, which sometimes curves upward and to one side at the tip when particularly long. Their numerous narrow pointed teeth are curved inward and become longer toward the distal end of the mandibles, becoming visible in larger individuals. Teeth become peg-like in older individuals from wear and accumulation of the cement layer. Their eyes are extremely small and visible as pinhole openings slightly above the upturned mouth. The external auditory meatus is larger than the eye opening and located slightly above it, a unique arrangement among odontocetes. The blowhole is a small slit oriented longitudinally, which is a rare but not unique configuration among cetaceans. A distinct median ridge begins anterior of the blowhole and bisects a convex melon, which becomes less rounded as the dolphin approaches adulthood. The dorsal fin is a low triangular hump with a slightly defined knob at the apex located about two-thirds of the body length posterior of the melon. Broad flippers are squared-off at the end with a crenellated margin, and the arm and hand bones are visible beneath the taut dorsal surface. Flukes are broad with a concave margin and distinct median notch. The opening for male genitals is located much closer to the umbilicus in relation to the anus when compared with most other cetaceans.

II. Taxonomy

Primitive features, such as intestinal cecum, and weak evidence from the nucleotide sequence of the cytochrome *b* gene suggest that *Platanista* may be a sister taxon to all other extant odontocetes (Rice, 1998). Although the superfamily Platanistoidea was previously considered to include three other monotypic genera—*Pontoporia*, *Lipotes*, and *Inia* (Kasuya, 1973; Zhou, 1982)—the genus *Platanista* is now recognized as the only extant member of the taxon (Rice, 1998). Pilleri *et al.* (1982) recognized two species of *Platanista* based on differences in the prominence of the nasal crests, caudal height of the maxillary crests, length of the lower transverse processes of the sixth and seventh cervical vertebrae, blood protein composition, and free-esterified cholestrin ratio in the lipids. Their arguments were unconvincing due to the small sample of adult specimens examined and the absence of statistical analyses (see Reeves and Brownell, 1989). Based on differences in tail lengths, Kasuya (1972) proposed that the susu and bhulan be considered subspecies; this was followed by Rice (1998).

III. Habitat

Susus and bhulans generally occur in eddy countercurrents downstream of channel convergences and sharp meanders, and upstream and downstream of mid-channel islands. They also occasionally occur in countercurrents induced by engineering structures such as bridge pilings and groynes. The affinity of *Platanista* for countercurrents is probably greatest in upstream tributaries where productivity is especially clumped and strong downstream currents restrict occupancy to the hydraulic refuge these areas provide (see Smith, 1993; Smith *et al.*, 1998).

IV. Population and Distribution

Although no rigorous range-wide surveys have been conducted, the aggregate populations of susu and bhulan are believed to number in the low thousands and few hundreds, respectively (Smith and Reeves, 2000). A map of historical distribution, charted by the 19th century British naturalist John Anderson (Anderson, 1879), shows the bhulan occurring throughout the Indus River mainstem and in the Sutlej, Ravi, Chenab, and Jhelum tributaries and shows the susu occurring throughout the Ganges–Brahmaputra–Megna and Karnaphuli river systems in Nepal, India, and Bangladesh. Anderson (1879) stated that the range of both species was only limited downstream by increasing salinity in deltas and upstream by rocky barriers or insufficient water. Their distribution has shrunk considerably since then, largely due to water development, which has blocked dolphin movements and degraded their habitat.

Bhulans currently occupies less than 700 km of the Indus mainstem (about one-fifth of the historic range), fragmented into three subpopulations by the Chashma, Taunsa, Guddu, and Sukkur barrages (Fig. 2; Reeves and Chaudhry, 1998). The largest subpopulation is located at the downstream end of the dolphins' range, between the Guddu and Sukkur barrages, with a reported count of 458 individuals (Mirza and Khurshid, 1996). Numbers decline progressively in upstream segments, despite their progressively larger geographical size. Counts of 143 and 39 individuals were reported between the Taunsa and Guddu and the Taunsa and Chasma barrages, respectively (Mirza and Khurshid, 1996). A few scattered individuals may still occur upstream of the Chashma barrage in the Indus and downstream of the Trimmu, Sidhnai, and Panjnad barrages in the Chenab, Ravi, and Sutlej rivers, respectively (Reeves *et al.*, 1991). A few bhulans may also stray below the Sukkur barrage, but these animals are lost to the overall population and have little chance of surviving due to lack of water.

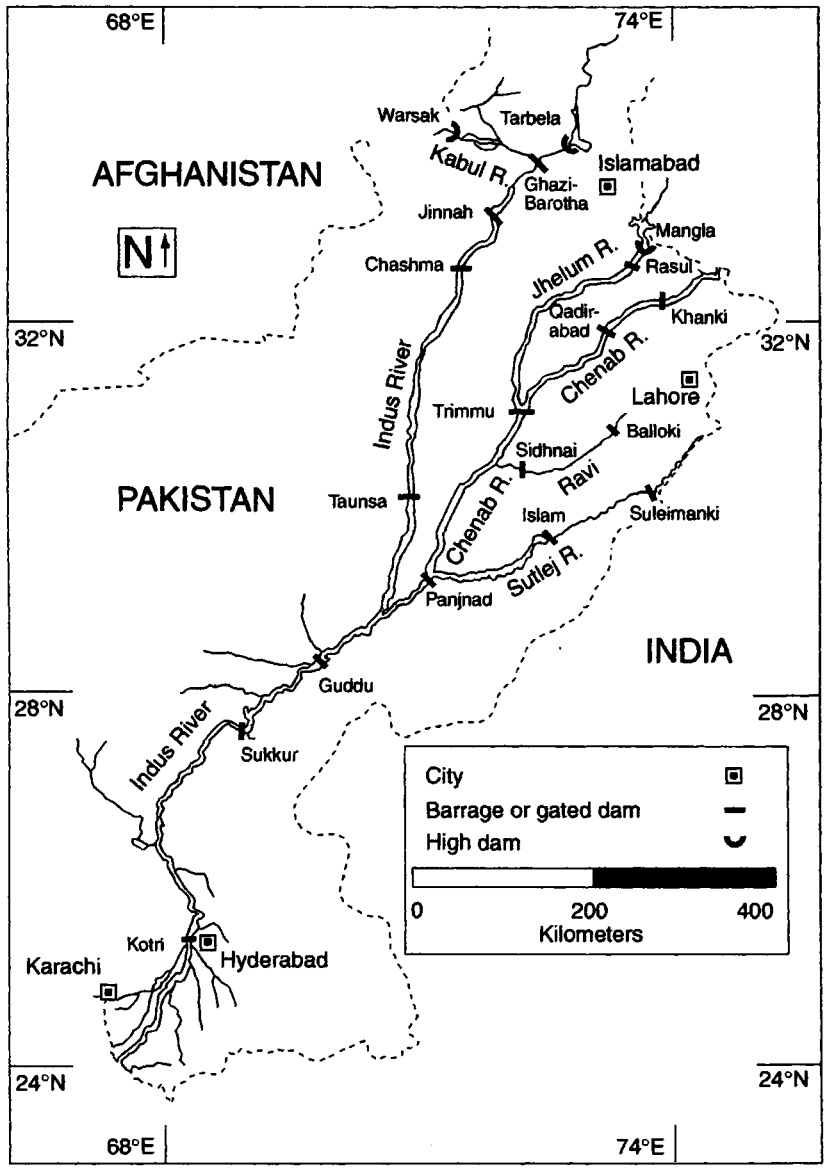

Figure 2 *Map of the Indus river system of Pakistan showing dams and barrages that have fragmented the population of bhulans and degraded their habitat.*

Historically, susus were found in the Ganges River as far upstream as Haridwar, about 100 km above their current range, and in the Yamuna River year round as far upstream as Delhi, probably about 400 km above their current low-water range (Fig. 3; Sinha *et al.*, 2000). In the Ganges mainstem, there are four extant subpopulations isolated between barrages. In the northern tributaries of the Ganges, of the six subpopulations that have been isolated above or between barrages, three have been extirpated (Gandak River above the Gandak barrage and Sarda River above the upper and lower Sarda barrages) (Sinha *et al.*, 2000) and one reduced to insignificant numbers (Kosi River above the Kosi barrage) (Smith *et al.*, 1994). In the Son River, a southern tributary of the Ganges, a small population of susus has been isolated above the Indrapuri barrage, and the dolphins no longer occur during the dry season for about 100 km below the barrage until the Ganges confluence (Sinha *et al.*, 2000). In southern Bangladesh, susus were documented in the Sangu River (Ahmed, 2000), which is connected to the Karnaphuli by the Sikalbaha–Chandkhali channel. There are occasional reports of dolphins remaining in the reservoir behind Kaptai Dam, but recent surveys produced no sightings.

V. Internal Anatomy

A. Bones

An extraordinary feature of the skull of *Platanista* is the projection of a maxillary crest, upward and forward, covering an air sinus that leads to the tympanic cavity. The crest slants to

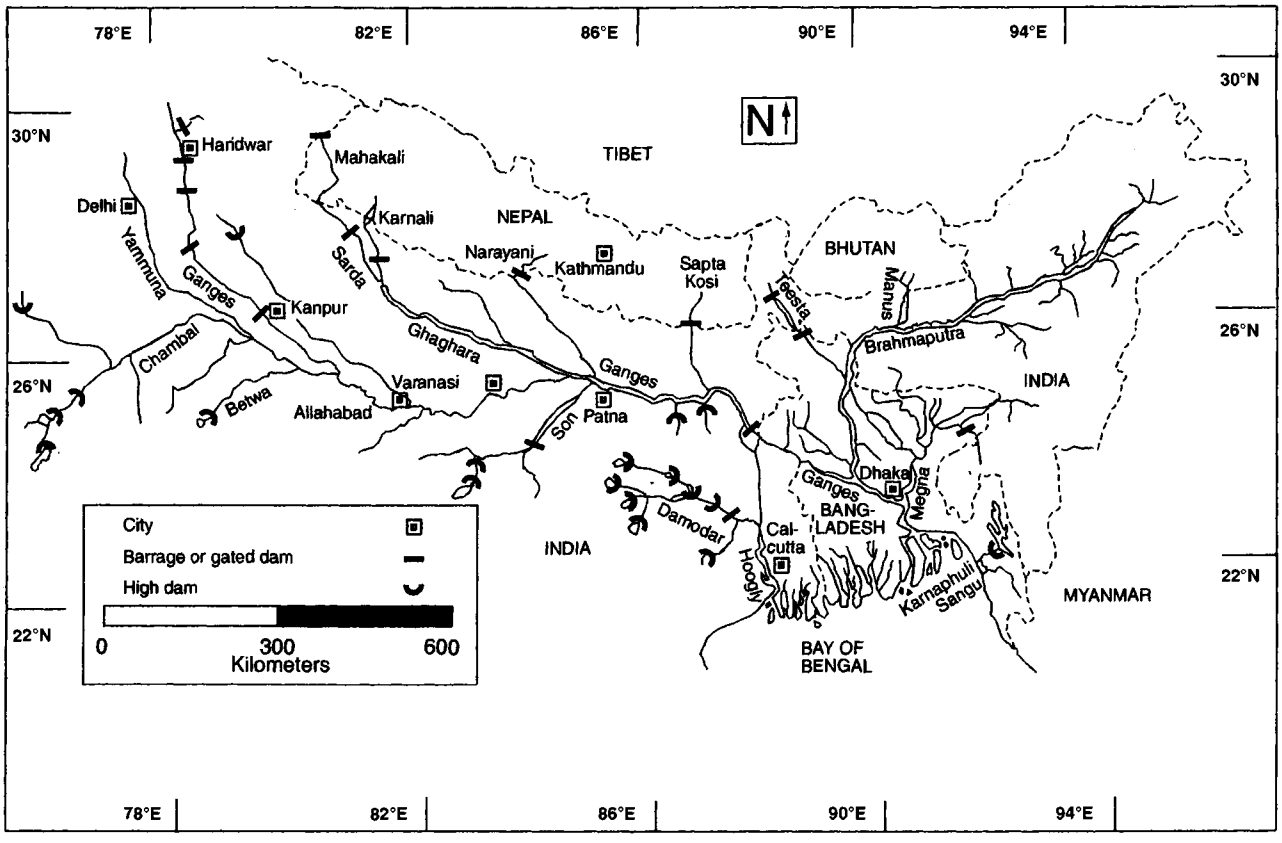

Figure 3 *Map of the Ganges–Brahmaputra–Megna and Karnaphuli–Sangu river systems of Nepal, India, and Bangladesh showing dams and barrages that have fragmented the population of susus and degraded their habitat.*

the left, which makes the SKULL among the most asymmetric of all odontocetes. Other skull features unique to *Platanista* include that the palatine is found in the nasal tube and that the pterygoids are external on the palate and enter the temporal fossa (Reeves and Brownell, 1989). The mandibular symphysis is laterally compressed, slightly upturned toward the end, and it constitutes as much as two-thirds the mandible length of adult females and a little more than half of adult males (Reeves and Brownell, 1989). Cervical vertebrae are unfused, allowing considerable neck movement. Postcranial skeletal features unique to *Platanista* include the location of costal facets of the thoracic vertebrae on the posterior margin of the centrum, a thicker ulna than radius, and the absence of ulnare and pisiform bones in the flippers.

B. Organs

The presence of a cecum between the large and the small intestines, a penis with erectile side lobes, nasolaryngeal air sacs that form a diverticulum of the eustachian tube, and a primitive and relatively unlobulated KIDNEY distinguish *Platanista* from other odontocetes. Compared to other dolphins, their BRAIN is small and neocortical development is low; however, subcortical components associated with acoustical functions are well developed. Their small eyes lack a crystalline lens, giving the dolphins a reputation for being blind, but their retinas do have light-gathering receptors (Herald *et al.*, 1969).

VI. Life History

Males attain sexual maturity at a body length of about 170 cm and physical maturity at 200–210 cm. Females attain sexual maturity at similar or slightly larger body lengths but physical maturity at about 250 cm. The generally larger rostrum of females accounts for this SEXUAL DIMORPHISM, which becomes evident at a body length of about 150 cm. Length at birth is estimated to be about 70 cm. Gestation lasts approximately 1 year, with possible peak birthing seasons in early winter and early summer. Young begin feeding on small prey at about 1 or 2 months and are weaned within a year (Kasuya, 1972).

VII. Behavior and Sensory Abilities

In 1968, three female bhulans were taken to the Steinhart Aquarium in San Francisco, where all died within 7 weeks. During the 1970s, the Swiss neuroanatomist Georgio Pilleri kept a total of seven bhulans in his institute at the University of Berne until they all died within a few years. Studies of these dolphins revealed exceptional aspects of *Platanista* behavior and sensory abilities. The dolphins vocalize almost constantly and swim on their sides in vertical circles. The dolphins continuously emit trains of high-frequency (15–150 kHz) echolocation clicks, interrupted by short pauses of 1–60 sec (Herald *et al.*, 1969). The click trains are focused in two highly directional fields, the dorsal one emitted directly from the melon

and the ventral one reflected downward by the maxillary crest, with an acoustic "scotoma" in between (Pilleri *et al.*, 1976). During a dive, the dolphins spin 90° on their lateral axis and position their head down, sweeping it back and forth in a scanning motion, while trailing one flipper along or slightly above the bottom. Shortly before surfacing, the dolphins reverse their spin and surface close to their original position and orientation.

In the wild, susus and bhulans are observed alone or in clusters of 2–3, but occasionally as many as 20 individuals. With the exception of mother–young pairs, the attracting force for these clusters may be more related to the patchy distribution of prey and hydraulic refuge than to survival or reproductive advantages gained by close social affiliations. Susus have been observed surfacing just inside of the upstream end of countercurrent boundaries where the eddies become aligned with main flow. Surfacing at this location may allow the dolphins to minimize energy outputs while monitoring foraging opportunities in the mainstream flow and center pool of the countercurrent (Smith, 1993).

VIII. Threats and Conservation

Both subspecies are classified by the IUCN as endangered. Perhaps the most significant threat to their survival is the existence of numerous dams and barrages that have severely fragmented populations and reduced the amount of suitable habitat. Dams are absolute barriers to dolphin movements. Subpopulations trapped above barrages are believed to lose dolphins when they move downstream during high water while the barrage gates are open. These dolphins probably cannot return due to strong hydraulic forces between the gates while they are open. This apparent involuntary attrition exasperates normal biological problems faced by small isolated populations. Water diverted by barrages, generally for irrigation and flood control, and abstracted by surface pumps and tube wells also results in dolphins competing with humans for the actual substance of their environment: fresh water. During the low-water season, the Indus and Ganges rivers become virtually dry downstream of the Sukkur and Farakka barrages, respectively.

Deliberate killing of bhulans for meat and oil was a traditional practice until at least the early 1970s (Pilleri and Zbinden, 1973–1974). HUNTING is now banned but poaching still occasionally occurs (Reeves and Chaudhry, 1998). Susus are killed by "tribals" in the upper Brahmaputra for their meat and by fishermen in the middle reaches of the Ganges for their oil, which is used as a fish attractant (Smith and Reeves, 2000). Similar to all cetaceans, the susu and bhulan are threatened by entanglement in fishing gear and vessel collisions. Their preferred habitat is often in the same location as primary fishing grounds and ferry crossings, which puts the dolphins at increased risk. The problem of accidental killing in fisheries will undoubtedly worsen as the demand for fish and fishing employment increases. POLLUTION may also be affecting the survival of both species, especially considering the decline in the flushing benefits of abundant water and the aggregate distribution of river dolphins in areas of intensive human use. As top CARNIVORES, the dolphins are particularly vulnerable to persistent contaminants (e.g., PCBs and DDTs), some of which are banned or strictly regulated in more developed countries but widely used in industry and agriculture of south Asia.

In 1974, the government of Sindh declared the Indus River between the Sukkur and Guddu barrages a dolphin reserve and the government of Punjab prohibited deliberate killing (Reeves *et al.*, 1991). Enforcement of these measures seems to have stopped the rapid population decline of the bhulan reported by Pilleri and Zbinden (1973–1974). The susu was perhaps the first cetacean to receive official protection from hunting when it was listed as a protected species in the Moral Edicts of King Asoka in India more than 2000 years ago. Susus currently receive legal protection from deliberate killing in all range states. The Vikramshila Gangetic Dolphin Sanctuary, Bihar, India, located between Sultanganj and Kahalgaon in the mainstem of the Ganges was designated as a protected area for dolphins in August 1991. In a few smaller tributaries, susus receive nominal protection by virtue of small portions of their habitat being included in or adjacent to national parks and sanctuaries.

Swimming

TERRIE M. WILLIAMS
University of California, Santa Cruz

The primary mode of locomotion for marine mammals, with the possible exception of polar bears (*Ursus maritimus*), is swimming. For dolphins, porpoises, and whales it is the only form of locomotion. The duration of swimming among these mammals may be as short as several seconds when moving between prey patches or as long as several months during seasonal migrations across entire ocean basins. Although swimming by marine mammals often appears effortless, it is in reality a delicate balance between precise body streamlining, exceptional thrust production by specialized propulsive surfaces, and locomotor efficiency (Fig. 1).

I. Hydrodynamics and Body Streamlining

One of the most characteristic features of marine mammals is a streamlined body shape. This is not surprising when one considers the forces that the animal has to overcome in order to move through water. When a swimmer moves through water a force, termed drag, acts backward on it resisting its forward motion. The equation describing total body drag is given by

Figure 1 *A bottlenose dolphin swimming at high speed on the water surface. The generation of waves by the dolphin's movements leads to increases in body drag and elevated energetic costs during surface swimming.*

$$\text{drag} = 1/2pV^2ACd, \quad (1)$$

where p is the density of the fluid, V is the velocity of the fluid relative to the body, A is a characteristic area of the body, and Cd is the drag coefficient (a factor that takes into account the shape of the swimmer). Four primary types of drag contribute to total body drag: (1) skin friction drag, which is a tangential force resulting from shear stresses in the water sliding by the body; (2) pressure drag, which is a perpendicular force on the body associated with the pressure of the surrounding fluid; (3) wave drag, which occurs when a swimmer moves on or near the water surface; and (4) induced drag, which is associated with water deflection off of hydrofoil surfaces such as fins, flukes, or flippers. Of these, pressure drag is the component most influenced by body streamlining in marine mammals. The more streamlined a body, the lower the pressure drag and consequently the lower the total body drag of the swimmer.

Mammals whose lifestyles or foraging habits involve prolonged periods of swimming have streamlined body shapes. In contrast to the lanky appearance and appendages of terrestrial mammals, marine mammals tend to have a reduced appendicular skeleton and characteristic teardrop body profile. External features that may disrupt water flow across the body are also reduced or absent in many species of marine mammal. These

features include the pinnae (external ears), limbs, and long fur. In highly specialized swimmers such as dolphins the skin contains microscopic ridges that help to direct the flow of water in a controlled manner down the body. All of these adaptations prevent the onset of turbulence in the water surrounding the swimmer, thereby reducing total body drag.

Hydrodynamic theory describes the streamlined body shape as one in which a rounded leading edge slowly tapers to the tail, and total length is three to seven times maximum body diameter. The ratio of these morphological measurements, termed the fineness ratio, can be written

$$\text{fineness ratio} = \frac{\text{maximum body length}}{\text{maximum body diameter}}. \qquad (2)$$

The optimum fineness ratio that results in minimum drag with maximum accommodation for volume is 4.5. Calculations of the fineness ratio for a wide variety of marine mammals show that many species have body shapes that conform to the ideal hydrodynamic range (Fig. 2). A review by Fish (1993) showed that many cetaceans, pinnipeds, and sirenians have body shapes with fineness ratios that range from 3.0 to 8.0. The species examined included seals, sea lions, and odontocete whales, which are considered by many to typify a streamlined body profile. However, even the mysticete whales with enlarged heads and jaws specialized for filter feeding maintain a streamlined body profile (Fig. 2).

Despite nearly ideal body streamlining, all marine mammals must contend with drag forces when moving through the water. These forces can be a considerable challenge for the swimmer and will influence how quickly the animal will be able to move. It is apparent from Eq. (1) that the velocity of the swimmer will have a large impact on total body drag. As the swimmer moves faster, body drag increases exponentially. An example of the relationship between total body drag and velocity is presented in Fig. 3 for the sea otter (*Enhydra lutris*). Whether the sea otter swims on the water surface or submerged, body drag increases with velocity. However, body position clearly affects the level of total body drag encountered by the sea otter. At all comparable swimming speeds, body drag is higher for the otter moving on the water surface than when it is swimming submerged.

The same results have been found for other swimmers, including humans and harbor seals (*Phoca vitulina*). In general, body drag for a swimmer moving on or near the water surface is four to five times higher than the level of drag encountered by the submerged swimmer moving at the same speed. Much of this increase in drag at the water surface is due to energy wasted in the formation waves. This can be avoided if the swimmer is able to submerge to a depth equivalent to three body diameters. For a seal or small whale with a maximum body diameter of 1 m, this would mean changing swimming position to at least 3 m in depth to avoid wave drag and the consequent

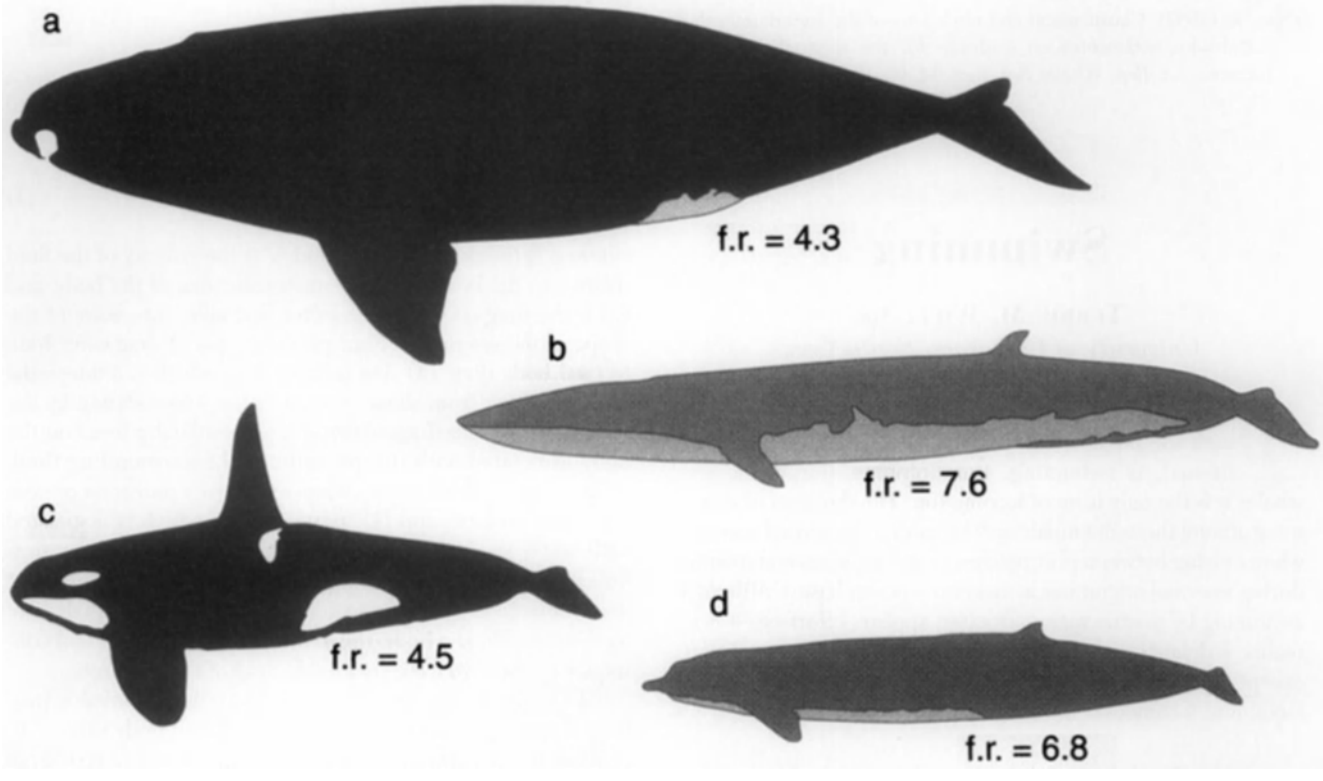

Figure 2 *Body shapes and fineness ratios for cetaceans. Shapes can range from the robust bowhead whale (a) to the long thin tapered body of the rorqual whales (b) and beaked whales (d). The killer whale (c) has the optimum shape in terms of fineness ratio and streamlining. From Berta and Sumich (1999), "Marine Mammals: Evolutionary Biology," Academic Press.*

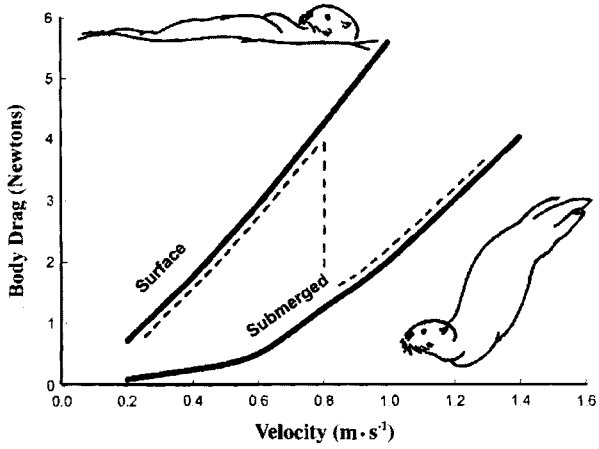

Figure 3 *Comparison of body drag for surface and submerged sea otters in relation to swimming speed. Note that at all comparable speeds, body drag of the sea otter on the water surface is higher than when the otter is submerged. The dashed line denotes the preferred swimming speeds of surface and submerged sea otters.*

elevation in total body drag. This is one of the reasons that swimming is comparatively difficult for humans—all of our performances take place on the water surface where wave drag, and hence total body drag, is the highest.

The ability to swim submerged for prolonged periods is one of the most important adaptations for increasing swimming efficiency and performance in marine mammals. The sea otter provides an excellent example of the advantage provided by this adaptation. Sea otters restrict prolonged periods of surface swimming to speeds less than 0.8 m · sec^{-1} and to a maximum body drag of 4.2 N (Fig. 3). For high-speed swimming, sea otters change to a submerged mode of locomotion. In doing so, drag is reduced by 3.5 times and the sea otter is able to reach speeds of 1.4 m · sec^{-1} before body drag once again exceeds 4.0 N. Thus, behavioral changes by the sea otter take into account the differences in drag associated with body position in the water and allow the animal to extend its range of swimming speeds. Several other behavioral strategies, such as porpoising and wave riding, are also used by marine mammals to avoid elevated body drag while swimming and are discussed in Section IV.

II. Kinematics

A hallmark of marine mammal swimming is the use of lift-based propulsion that allows thrust to be generated through the entire stroke cycle. This capability is found in highly adapted marine species such as pinnipeds and cetaceans. It contributes to an increase in locomotor efficiency in marine mammals, especially when compared to the inefficient drag-based swimming styles of humans and terrestrial mammals (Fig. 4).

Marine mammals use a wide variety of swimming styles to move through the water (Table I). The most terrestrial species of this group, the POLAR BEAR and sea OTTER, swim by alternate strokes of the forelimbs or hindlimbs, respectively. Polar bears use a dog style of forelimb paddling with the hindlimbs dragged passively behind or used as an aid to steering. Sea otters are unique among marine mammals in their ability to lie on their backs during surface swimming. Propulsion is provided by either simultaneous or alternate strokes of the hindlimbs. When on the surface, sea otters can also swim ventral surface (belly) down using the hind paws for propulsion. The front paws are held against the submerged chest and do not play a role in propulsion during this mode of swimming. Stroke frequency

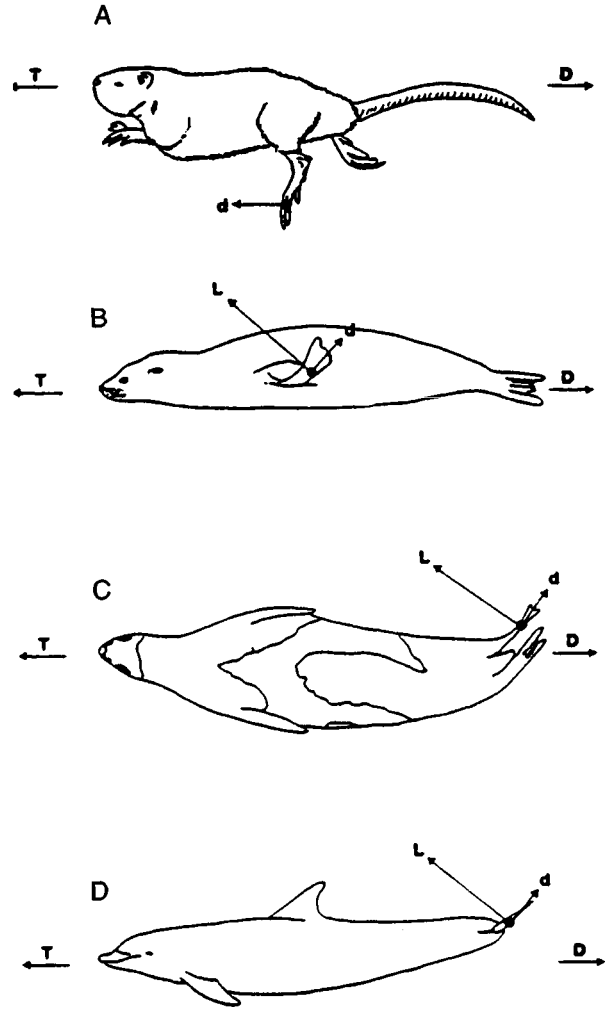

Figure 4 *Swimming modes for semiaquatic and marine mammals. The muskrat (A) is a semiaquatic mammal that uses drag-based propulsion by paddling its hind feet. Otariids (B), phocid seals (C), and cetaceans (D) use life-based propulsion that may involve fore flippers (sea lion), lateral body undulation (seal), or dorsoventral undulation (dolphin). Major forces on the animals and propulsive surfaces are shown. T denotes thrust, and D shows the direction of body drag on the animals. L and d illustrate lift and drag forces on the appendages, respectively. From Fish (1993).*

TABLE 1
A Comparison of Swimming Characteristics for Four Major Classes of Marine Mammals

	Sea otter	*Otariid*	*Phocid*	*Small cetacean*
Routine speed (m/sec)	<0.8 (surface) <1.4 (submerged)	2.0–3.0	1.2–2.0, sprints to 4.0	2.0–4.0, sprints to 10.0
Hydrodynamics	Surface/submerged	Submerged	Submerged	Submerged
Kinematics				
Mode	Paddle, row (surface) Undulate (submerged)	Pectoral	Lateral Carangiform	Dorsoventral Thunniform
Energetics[a]				
COT measured / COT predicted	12.0 (surface) 6.0 (submerged)	2.3–4.0	2.3–4.0	2.1–2.9

[a]The energetic cost of transport (COT) was measured for animals swimming in a flume or swimming freely in open water. The ratio of these values and the predicted values for fish of similar body mass are presented.

has been measured for swimming sea otters and ranges from approximately 30 to 80 strokes per minute while swimming on the water surface.

Polar bears and sea otters are the only marine mammals that rely primarily on drag-based modes of swimming. These modes of swimming have two distinct phases during the stroke cycle: a power phase when thrust is produced and a recovery phase when the foot is repositioned for the next stroke. During the power phase the foot is moved backward relative to the body. Drag created by this motion is subsequently translated into thrust and the animal moves forward through the water. The enlarged hind flippers of sea otters and fore paws of polar bears enable the animals to increase propulsive efficiency by moving a large mass of water during this power phase. The recovery phase of the stroke is only used to bring the limb back to its starting position and occurs without the generation of thrust. Because thrust is produced only during part of the stroke cycle, drag-based modes of swimming are comparatively inefficient.

When sea otters want to move quickly through the water they switch to an undulatory mode of swimming involving dorsoventral body flexion and simultaneous movements of paired hind flippers. The tail and hind flippers are held straight back and trail the undulatory movements of the trunk. The stroke frequency of sea otters remains relatively constant at 55 strokes per minute during submerged undulatory swimming, which suggests that underwater speed is elevated by increasing stroke amplitude.

As observed for submerged swimming sea otters, dolphins and whales use undulatory modes of propulsion. The primary propulsive movements of all cetaceans occur in the vertical plane with the posterior third of the body undulating in a dorsoventral direction. Termed thunniform swimming or carangiform swimming with a semilunate tail, this mode of locomotion is characterized by an undulatory wave that travels with increasing amplitude down the body, caudal peduncle, and finally the flukes (Fig. 5). "Semilunate" refers to the crescent shape of the flukes. This mode of propulsion is shared by other fast-swimming vertebrates, including tuna, hence the name "thunniform." Undulatory propulsion in cetaceans is considered highly efficient and can generate high levels of thrust on both the upstroke and the downstroke. There is no recovery phase and propulsion can be produced throughout the stroke cycle. Stroke frequency using this mode of swimming varies with the speed and size of the cetacean. The range of stroke frequencies for bottlenose dolphins swimming in a pool is 60–180 strokes · min^{-1}. Stroke frequency decreases with increasing body size among the cetaceans. Thus, we find that the largest species of swimming mammal, the 100-ton blue whale (*Balaenoptera musculus*), uses stroke frequencies that are only one-tenth of the range observed for bottlenose dolphins (*Tursiops* spp.). Recent measurements of the stroke frequency of blue whales ascending during a dive were 6–10 strokes · min^{-1}.

Swimming by pinnipeds differs markedly among EARED SEALS (otariids) and true seals (the phocids). Otariids use pectoral appendages to generate propulsive forces during swimming, with the hind flippers trailing passively or occasionally used for steering. In this way, sea lions and fur seals resemble penguins and sea turtles during swimming. Detailed kinematic analyses have been conducted for California sea lions (*Zalophus californianus*) swimming in a flume. These studies revealed three distinct phases to the stroke: (1) the power phase, (2) a paddle phase, and (3) a recovery phase. The majority of thrust is produced during the paddle phase when the fore flippers are moved quickly and forcibly from the water flow to the sides of the animal's body. Stroke frequency for these sea lions increased with swimming speed and ranged from 15 to 50 strokes · min^{-1} as the animals increased speed from 0.5 to 3.0 m · sec^{-1}. In addition to stroke frequency, sea lions increase the amplitude of the fore flipper stroke during high-speed swimming.

When viewed in cross section, the fore flipper of the sea lion resembles a hydrofoil. This specialized shape allows the flipper to produce thrust during the power and recovery phases of the stroke cycle. As found for cetaceans, the specialized flip-

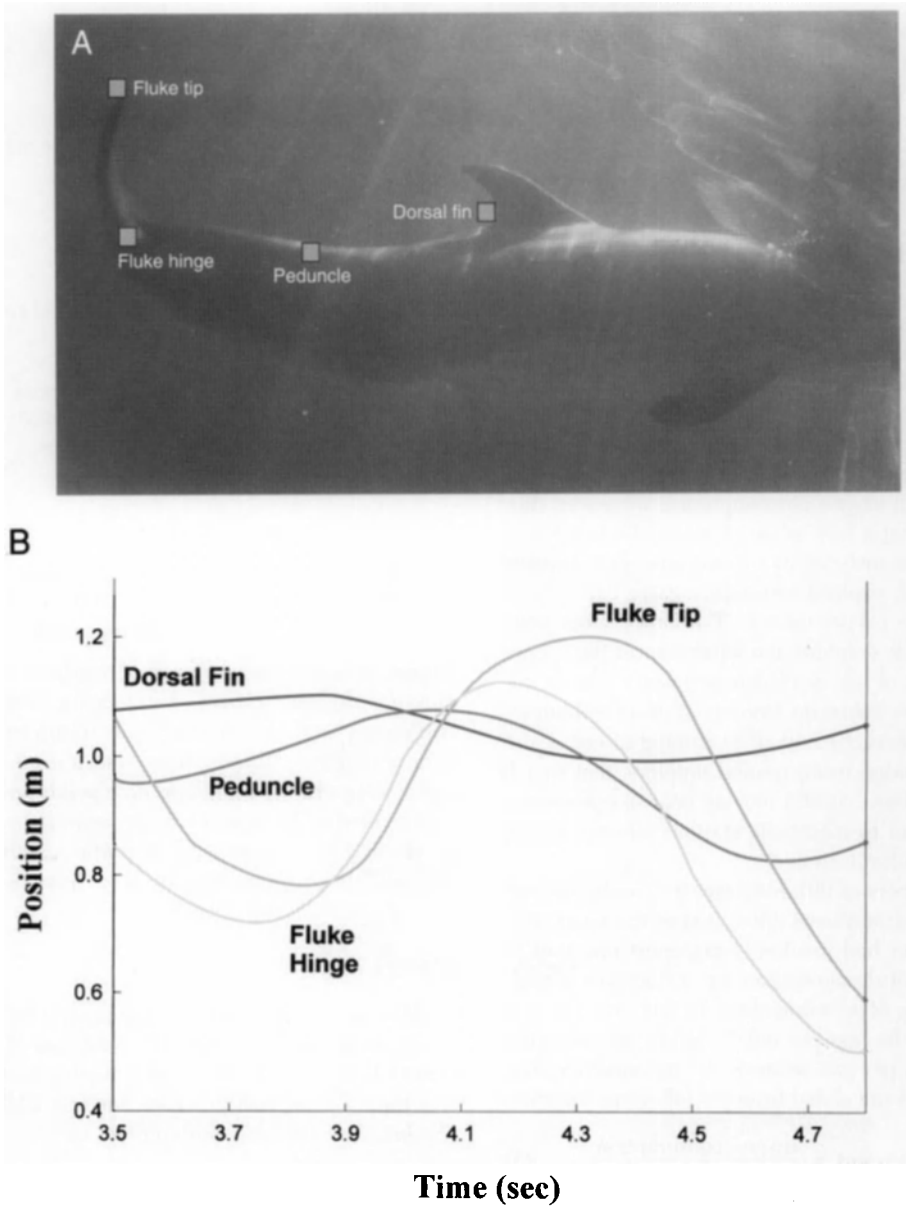

Figure 5 *Video image (A) and range of movement (B) of four anatomical sites during a single stroke for a swimming bottlenose dolphin. Squares correspond to the lines illustrating the movements for each site. Note the traveling wave as it passes from the dorsal fin to the peduncle, fluke hinge, and finally the fluke tip. From Skrovan* et al. *(1999).*

per movements of otariids result in thrust production throughout the stroke cycle and contribute to overall locomotor efficiency. Several other advantages are provided by fore flipper propulsion. These include stability at slow speeds and maneuverability at high speeds. Consequently, otariids are champion underwater acrobats and are capable of rapid changes in direction and acceleration.

Phocid seals and WALRUSES (*Odobenus rosmarus*) differ from otariids in terms of swimming style and rely on alternate sweeps of the hind flippers for propulsion. In addition to the flippers, the posterior half of the body flexes during each stroke with the result that body flexion provides nearly 90% of the change in amplitude during the stroke cycle. In phocid seals, both hind flippers are swept in the same direction as the posterior portion of the body during each half of the stroke cycle. The leading flipper remains closed and the trailing flipper maximally expands during the sweep to one side. Once the flippers have moved to the maximum lateral position, the flippers switch their open and closed positions in preparation for the reverse lateral sweep. By reversing the role of each flipper during lateral

sweeps, one flipper is able to provide thrust while the other flipper recovers. The result, once again, is the ability to produce propulsive thrust during the entire stroke cycle. Stroke frequency in phocids increases linearly with swimming speed. For harbor seals trained to swim at 1.0 to 1.4 m · sec^{-1} in a water flume, stroke frequency ranged from 60 to 78 strokes · min^{-1}.

III. Energetics

The energetic cost of swimming has been measured for numerous species of semiaquatic and marine mammals using a wide variety of techniques. Smaller swimmers, such as sea otters, seals, and sea lions, have been studied while they swam against a current in water flumes. Similar to placing a human on a treadmill, flume studies have enabled scientists to measure how much energy a swimmer expends while moving at different speeds. Often oxygen consumption is measured during these tests by using a face mask or metabolic hood connected to an oxygen gas analyzer. By training animals to breathe into a metabolic hood, expired respiratory gases can be collected and analyzed for oxygen content. For larger, more powerful swimmers, such as dolphins and whales, most flumes are not adequate in terms of size or challenging water speeds. Instead, investigators have relied on a variety of novel techniques for determining the energetic cost of swimming in cetaceans. Techniques have included using trained dolphins that match their swimming speed to that of a moving boat in open water or having whales swim to metabolic stations where expired gases can be collected for analysis.

To compare swimmers of different size, it is useful to convert the metabolic measurements into a cost of transport. Defined as the amount of fuel it takes to transport one unit of body weight over a unit distance, the cost of transport is analogous to the fuel rating of an automobile. In this case, the cost of transport indicates the "gas per mile" used by the swimmer rather than the "miles per gas" achieved by automobiles. The total cost of transport is calculated from the following equation:

$$\text{total cost of transport} = \frac{\text{oxygen consumption}}{\text{swimming speed}}, \qquad (3)$$

where oxygen consumption is in $mlO_2 \cdot kg^{-1} \cdot sec^{-1}$ and speed is in m · sec^{-1}, which results in a cost of transport in $mlO_2 \cdot kg^{-1} \cdot m^{-1}$. These values are usually converted to an energetic term and are expressed as Joules expended per kg of body weight per meter traveled ($J \cdot kg^{-1} \cdot m^{-1}$). The conversion calculation assumes a caloric equivalent of 4.8 kcal per liter of oxygen consumed and a conversion factor of 4.187×10^3 J/kcal.

Comparisons of the cost of transport for a wide variety of mammalian swimmers indicate that swimming is energetically expensive for mammals in comparison to fish. The total cost of transport for swimming mammals can also be divided into two distinct groups: semiaquatic mammals and marine mammals (Fig. 6). Swimming costs for semiaquatic mammals, such as minks, muskrats, and humans, are two to five times higher than observed for marine mammals. These high energetic swimming costs are attributed to a wide variety of factors, including elevated body drag associated with a surface swimming position (Fig. 3) and low propulsive efficiency associated with drag-based propulsion.

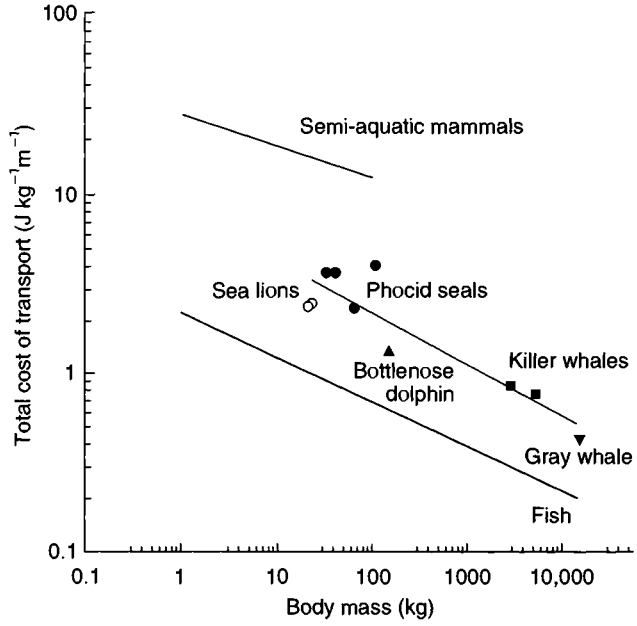

Figure 6 *Total energetic cost of transport in relation to body mass for different classes of swimmers. Marine mammals include gray seals and harbor seals, California sea lions, bottlenose dolphins, killer whales, and a gray whale. The least-squares regression through the data points for marine mammals is presented in the text. This regression is compared to the regressions for swimming semiaquatic mammals (upper solid line) and the predicted regression for salmonid fish (lower solid line). From Williams (1999).*

Mammals specialized for swimming demonstrate comparatively lower energetic costs. The total cost of transport in relation to body mass for swimming marine mammals ranging in size from a 21-kg California sea lion to a 15,000-kg gray whale (*Eschrichtius robustus*) is described by

$$\text{total cost of transport} = 7.79\ \text{mass}^{-0.29}, \qquad (4)$$

where the cost of transport is in $J \cdot kg^{-1} \cdot m^{-1}$ and body mass is in kilograms. Interestingly, the style of swimming used by marine mammals did not affect the cost of transport relationship. Species and swimming styles represented in this equation include sea lions using pectoral fins for propulsion, phocid seals using lateral undulation of paired hind flippers, and odontocete and mysticete whales using dorsoventral undulation of flukes.

As illustrated in Fig. 6, the energetic cost of swimming for marine mammals is greater than predicted for salmonid fish of similar body size. Despite specialization of the body and propulsive surfaces for aquatic locomotion, the cost of transport for swimming by seals and sea lions is 2.3 to 4.0 times higher than predicted for swimming fish. Values for cetaceans are somewhat lower and range from 2.1 to 2.9 times values predicted for fish. Differences in the total cost of transport between marine mammals and fish are due in part to the amount of energy expended for maintenance functions, particularly thermoregula-

tion and the support of a high core body temperature. As endotherms, mammals expend more energy to support the production of endogenous heat than ectothermic fish. In addition, many marine mammals show exceptionally high metabolic rates while resting in water in comparison to terrestrial mammals resting in air. A consequence of these high maintenance costs is an overall increase in the total energy expended during swimming, especially when compared to fish.

IV. Swimming Speeds and Behavior

Although body size varies considerably among marine mammals from the 20-kg sea otter to the 122,000-kg blue whale, routine swimming is limited to a surprisingly narrow range of speeds. Many species of marine mammal routinely swim between approximately 1.0 and 3.6 m · sec^{-1} regardless of body size (Fig. 7). Within this range, pinnipeds generally select slower routine traveling speeds than cetaceans, and mysticete whales swim slower than odontocetes. For example, average swimming speeds for a wide variety of otariids and phocids range from 1.3 to 2.0 m · sec^{-1}. The massive mysticete whales are only slightly faster; routine speeds for this group of marine mammals range from 2.1 to 2.6 m · sec^{-1}. Although they are not the largest marine mammals, odontocetes tend to move the fastest during routine travel. The slowest of the odontocetes represented in Fig. 7 was the beluga whale (*Delphinapterus leucas*) with a routine speed of 1.8 m · sec^{-1}. In comparison, the killer whale (*Orcinus orca*) demonstrates the fastest routine speed of the marine mammals measured to date and averages 3.6 m · sec^{-1} during casual swimming. These speeds are even more remarkable when compared to the efforts of humans. The routine speed of humans during freestyle swimming is approximately 1.0 m · sec^{-1}, about the same speed as a sea otter swimming underwater.

As would be expected, the sprinting speeds of marine mammals are considerably faster than routine speeds and show much variation among the species measured. Most of the information regarding sprint swimming performance in marine mammals is for cetaceans. However, the speed of adult Weddell seals (*Leptonychotes weddellii*) chasing fish beneath the Antarctic sea ice has been measured and was found to exceed 4.0 m · sec^{-1} during the hunt. Among cetaceans, sprint speeds are even higher. The range of sprinting speeds measured for mysticete whales is 4.1 to 13.3 m · sec^{-1} (Fig. 7); sprint swimming by odontocetes is within the upper end of this range and averages 6.1 to 12.5 m · sec^{-1}. Killer whales remain the fastest of the odontocetes measured and can sprint at 12.5 m · sec^{-1}. This is nearly six times faster than the maximum performance of human swimmers in Olympic sprint competition.

Because marine mammals must surface periodically to breathe, they are subject to high levels of drag associated with the effects of wave formation and splashing, especially during high-speed swimming. To help minimize body drag and energetic costs during these surface intervals, marine mammals have developed a number of unique behavioral strategies to accommodate

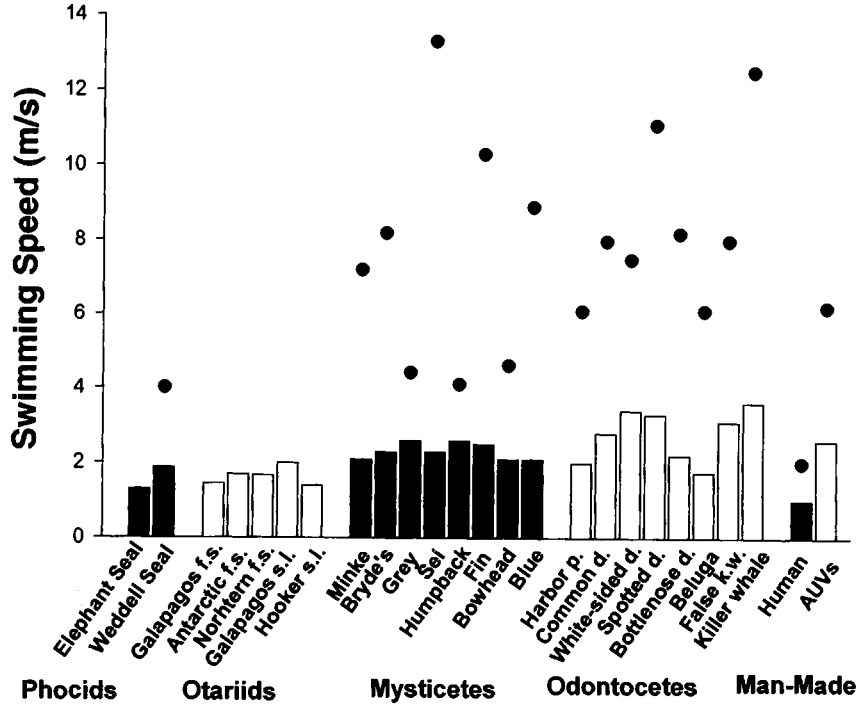

Figure 7 *Swimming speeds for marine mammals. Routine speeds of phocid seals, otariids, mysticetes, odontocetes, humans, and autonomous underwater vehicles (AUVs) are shown. Filled circles above the bars denote the sprinting speeds recorded for each species. Note the similar range of routine speeds for these marine mammals regardless of body size.*

breathing while swimming fast. Porpoising is one such highly visible behavioral strategy used by small cetaceans and some pinnipeds moving at high speed near the water surface. Rather than stroke continuously, the animals leap into the air and simply avoid the elevated wave drag that occurs when swimming near the water surface to breathe. Theoretically, this behavior results in an energetic savings to the animal, although the cost of surface swimming versus leaping has yet to be measured.

Wave riding is another strategy that enables the swimmer to avoid the work of continuous stroking while moving near the water surface. In a study involving bottlenose dolphins trained to swim freely or wave ride next to a moving boat, investigators found that heart rate, respiration rate, and energetic cost were reduced for animals riding the bow wave of the boat. This behavior enabled the dolphins to nearly double their forward traveling speed with only a 13% increase in energetic cost. Consequently, it is not surprising that marine mammals routinely ride waves generated by the wind, surf, the wake of boats, and even large whales. What appears to be an amusing activity also provides an energetic benefit to the swimmer.

Although energetically advantageous when swimming near the water surface, both wave riding and porpoising have been described for only a limited number of marine mammal species moving at high speeds. These locomotor strategies are not possible during slow transit, in large marine mammals such as elephant seals (*Mirounga* spp.) and whales, or in polar regions where ice covers the water surface. Instead, transit swimming is often accomplished by a sawtooth series of sequential dives that allow the animals to remaining submerged except for brief surface intervals to breathe.

V. The Special Case of Swimming at Depth

Most of our information about swimming in marine mammals is from animals moving near the water surface. However, the majority of swimming by these animals occurs at depth in conjunction with diving. When descending or ascending during a dive, marine mammals must contend with buoyant forces and hydrostatic pressure, as well as body drag. As discussed earlier, drag forces resist both forward progression and limb movements of the swimmer. In contrast, buoyant forces act in a vertical direction in the water column and result from the weight, volume, and compressibility of the tissues and air spaces of the animal's body. Hydrostatic pressure results from the weight of the water column above the marine mammal.

The magnitude of buoyant forces and hydrostatic pressure on the swimming marine mammal will depend on where in the water column activity takes place. Hydrostatic pressure increases progressively by 1 ATM for every 10.1 m an animal descends in the water column. This will have a profound effect on compressible spaces or tissues, and hence buoyancy of the animal, especially for marine mammals that may descend and ascend hundreds of meters during the course of a dive. In addition, seasonal changes in blubber content, pregnancy, and lactation will have an effect on the overall buoyancy of the marine mammal.

A consequence of the interrelationships among depth, buoyancy, hydrostatic pressure, and body drag is that the physical forces influencing the animal swimming horizontally near the water surface are very different from those encountered by the diving animal moving vertically through the water column. Detailed studies on diving common bottlenose dolphins and elephant seals have shown that the animals are positively buoyant near the water surface and that buoyancy decreases as the animal descends during the dive. For example, the buoyancy of a bottlenose dolphin changes from positive (24 N) when near the water surface to negative (−26 N) once the animal exceeds 70 m in depth.

These changes in buoyancy are associated with changes in lung compression due to the increase in hydrostatic pressure as marine mammals descend on a dive. Thus, as dolphins, whales, and seals dive, hydrostatic pressure increases and the lungs progressively collapse with the result that overall buoyancy is changed. These marked changes in physical forces with depth affect both locomotor behavior and energetics of the marine mammal as it descends and ascends during a dive (Fig. 8).

Until recently, it was not possible to observe the swimming modes of marine mammals during deep dives. With the development of miniaturized video cameras and instrumentation worn by free-ranging marine mammals, new information about swimming at depth has been obtained (Fig. 9). Videos have revealed that bottlenose dolphins, elephant seals, Weddell seals, and blue whales switch between different modes of swimming during the dive, much like terrestrial mammals switch between gaits. Dive descents usually began with a period of continuous stroking. Once the marine mammals reach 70–80 m in depth they change to a passive glide for the remainder of the descent. For deep divers such as phocid seals, these gliding periods can be quite long. For example, prolonged gliding periods exceed 6 min for Northern elephant seals (*M. angustirostris*) traveling to nearly 400 m and Weddell seals descending to 540 m beneath the Antarctic sea ice. Nearly 80% of the descent of diving seals may be spent gliding passively rather than swimming actively on dives exceeding 200 m in depth.

The ascent portion of a dive requires more effort by marine mammals when compared to the descent. The beginning of the ascent represents the period of greatest swimming effort for mammalian divers. During this period, many species of pinniped and cetacean use sequential, large amplitude strokes to begin moving upward. As the ascent continues, the physical forces impacting the diver are once again altered as they move through the water column. Hydrostatic pressure decreases on ascent. Consequently, the lungs are able to reinflate and the buoyancy of the marine mammal increases. Swimming behavior reflects these changes with the result that the continuous stroking phase is followed by a stroke and glide mode of swimming, and finally a brief glide to the water surface.

By altering the mode of swimming to account for changes in the physical forces that occur during a dive, marine mammals are able to conserve limited oxygen reserves during submergence. One study investigating the metabolic rates of Weddell seals diving from an ice hole found that the incorporation of prolonged glides enabled seals to reduce the energetic cost of individual dives by 9–60%. Such an energetic savings could make the difference between completing the dive aerobically or anaerobically and can increase the time available for hunting or avoiding predators.

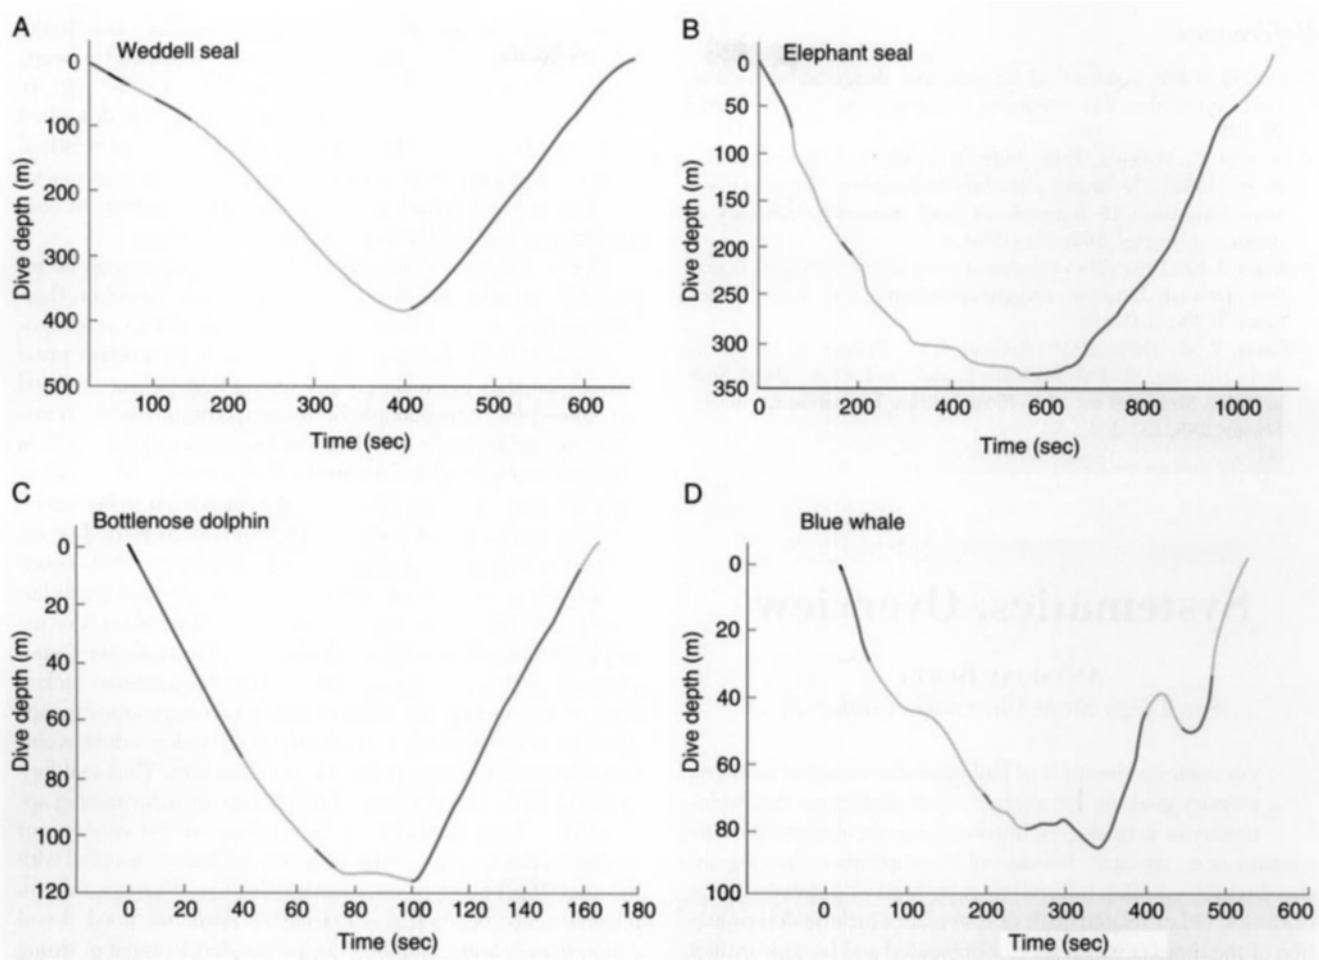

Figure 8 *Swimming and gliding activity of four species of diving marine mammal. Representative deep dives are presented for the Weddell seal (A), elephant seal (B), bottlenose dolphin (C), and blue whale (D). Each curve shows dive depth in relation to time elapsed during the dive. The shade of the line corresponds to stroking (black) and gliding (gray) periods. For each species the descent was characterized by prolonged periods of gliding. From Williams* et al. *(2000).*

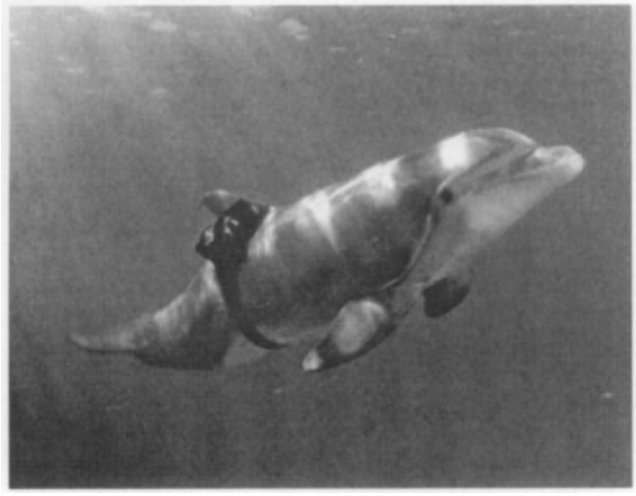

Figure 9 *A bottlenose dolphin carries a video camera to record its swimming movements during deep dives. Courtesy of Kevin McDonnell.*

In summary, these studies demonstrate that swimming can be energetically expensive for mammals. Marine adapted species, including sea otters, pinnipeds, and cetaceans, have undergone marked morphological, physiological, and behavioral changes to increase their swimming efficiency. An especially important adaptation that distinguishes marine mammals from semiaquatic mammals is the ability to remains submerged for prolonged periods when swimming. However, prolonged submergence also requires specialized physiological responses associated with oxygen loading and utilization. A major benefit of these adaptations is a capacity for aquatic performance by marine mammals that far exceeds those of semiaquatic mammals and the best Olympic efforts of humans.

Systematics, Overview

ANNALISA BERTA
San Diego State University, California

Systematics is the study of biological diversity that has as its primary goal the reconstruction of phylogeny, the evolutionary or genealogical history of a particular group of organisms (e.g., species). Because of its emphasis on phylogeny, this discipline is often referred to as phylogenetic systematics or cladistics. Other related goals of systematics include determination of the times at which species originated and became extinct and the origin and rate of change in their characteristics. An important component of systematics is taxonomy, the identification, description, nomenclature, and classification of organisms. Systematics provides a framework for interpreting patterns and processes in evolution using explicit, testable hypotheses.

The rapid pace of research on marine mammals has resulted in renewed interest in their systematics. Phylogenetic systematic methodology as introduced here has gained near universal acceptance. [For a general introduction to the topic readers are referred to texts by Eldredge and Cracraft (1980), Wiley (1980), and Wiley *et al.* (1991).] In addition to their use in elucidating evolutionary relationships, phylogenies are now recognized as powerful tools for unveiling evolutionary patterns of marine mammal diversity in ecological and behavioral settings.

I. Basic Tenets of Phylogenetic Systematics

The recognition of patterns of relationship among SPECIES is founded on the concept of evolution. Patterns of relationship among species are based on changes in the characters of an organism. Characters are diverse, heritable attributes of organisms that include DNA base pairs, anatomical and physiological features, and behavioral traits. Two or more forms of a given character are termed *character states*. For example, among pinnipeds, the character contact between maxillary and frontal bones consists of three character states: (1) V shaped (in bears, extinct desmatophocids, *Enaliarctos*, and phocids), (2) W shaped (in otariids), and (3) transverse (walruses) as described by Berta and Sumich (1999). In the establishment of relationships among groups of organisms, phylogenetic systematics emphasizes evolutionary novelties (derived characters) in contrast to ancestral similarities (primitive characters).

The evolutionary history of a group of organisms can be inferred by sequentially linking species together based on their common possession of derived characters, also known as *synapomorphies*. If derived characters are unique to a particular taxon rather than showing relationships among taxa they are termed *autapomorphies*. An example of an autapomorphy is the transverse contact between maxillary and frontal bones seen only in walruses among pinnipedimorphs (living pinnipeds and their fossil relatives). Derived characters are considered to be *homologous*, a similarity that results from common ancestry. For example, the flipper of a seal and that of a walrus are homologous because their common ancestor had flippers. In contrast to homology, a similarity not due to homology is *homoplasy*. For example, the flipper of a pinniped and that of a whale are homoplasious as flippers because their common ancestor lacked flippers. Homoplasy may arise in one of two ways: convergence (parallelism) or reversal. *Convergence* is the independent evolution of a similar feature in two or more lineages. Thus seal flippers and whale flippers evolved independently as swimming appendages; their similarity is homoplasious by convergent evolution. *Reversal* is the loss of a derived feature coupled with the reestablishment of an ancestral feature. For example, in phocine seals (bearded seal *Erignathus barbatus*, hooded seal *Cystophora cristata*, and the Phocini) the development of strong claws, lengthening of the third digit of the foot, and deemphasis of the first digit of the hand are character reversals because none of them characterize phocids ancestrally but are present in terrestrial arctoid CARNIVORES, common ancestors of PINNIPEDS (Berta and Sumich, 1999).

Relationships among organismal groups are commonly represented in the form of a *cladogram*, a branching diagram that conceptually represents the best estimate of phylogeny (Fig. 1). Derived characters are used to link *monophyletic* groups, groups of taxa that consist of a common ancestor plus all descendants of that ancestor (referred to as a *clade*). For example, a hypothesis of relationships among pinnipedimorphs (inclusive group that includes all pinnipeds and their close fossil relatives) based on morphologic characters proposes that phocid seals (Phocidae) and an extinct lineage (Desmatophocidae) are more closely related to each other than either is to walruses (Odobenidae). Fur seals and sea lions (Otariidae) are positioned as the next closest relative to this clade (walruses + desmatophocids + phocids) with the fossil taxon *Enaliarctos* recognized as the most *basal* lineage (Berta and Sumich, 1999; Fig. 1). According to this hypothesis, relationships among pinnipedimorphs are depicted as sets of nested hierarchies. In this case, four monophyletic groups can be recognized. The most exclusive monophyletic group is that formed by phocid seals and desmatophocids, as this clade shares derived synapomorphies not also exhibited by walruses, otariids, or *Enaliarctos*. At

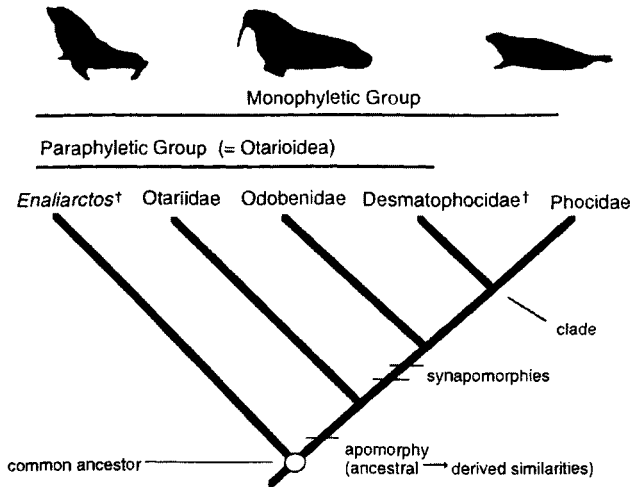

Figure 1 *Hypothesis of pinnipedimorph relationships. †, extinct taxa.*

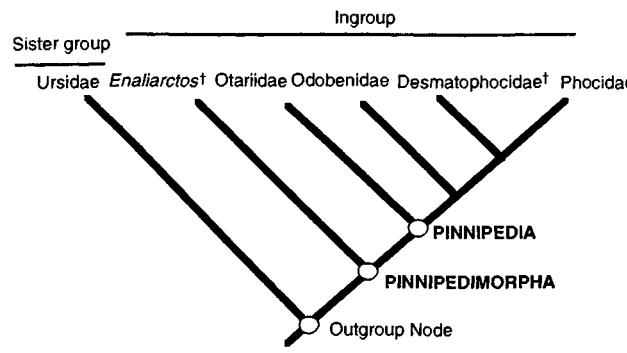

Figure 2 *Pinniped relationships with ingroup and outgroups identified. †, extinct taxa.*

the other extreme, the most inclusive monophyletic group is that formed by *Enaliarctos* + Otariidae + Odobenidae + Desmatophocidae + Phocidae.

The task in inferring a phylogeny for a group of organisms is to determine which characters are derived and which are ancestral. If the ancestral condition of a character or character state is established, then the direction of evolution from ancestral to derived can be inferred, and synapomorphies can be recognized. The methodology for inferring the direction of character evolution is critical to cladistic analysis. *Outgroup comparison* is the most widely used procedure. It relies on the argument that a character state found in close relatives of a group (the outgroup) is likely to be the ancestral or primitive state for the group of organisms in question (the ingroup). Usually more than one outgroup is used in an analysis, the most important being the first or genealogically closest outgroup to the ingroup called the sister group (Maddison *et al.*, 1984). For example, among pinnipedimorphs the ingroup includes the Phocidae (seals), the Desmatophocidae (extinct seal relatives), the Otariidae (fur seals and sea lions), the Odobenidae (walruses) and the fossil taxon *Enaliarctos*. The Phocidae is hypothesized as the sister group of the Desmatophocidae and these taxa together form the sister taxon to the Odobenidae. The Otariidae and *Enaliarctos* are positioned as sequential sister taxa. In the hypothesis presented here, bears (Ursidae) are positioned as the closest pinniped outgroup (Fig. 2), although alternate hypotheses support pinnipeds as either allied with MUSTELIDS or as having an unresolved ancestry with arctoids (ursids, mustelids, and procyonids).

II. Phylogeny Reconstruction

The first step in the reconstruction of phylogeny of a group of organisms is selection and definition of characters and character states for each taxon (e.g., species). Next, the characters and their states are arranged in a data matrix (see Table I). Characters can be further distinguished; those with two states are *binary*, whereas characters with three or more states are *multistate*. For each character, ancestral and derived states are determined. The determination of character state, whether ancestral or derived (also called *polarity* assessment), is done using outgroup comparison. For example, if the distribution of

Ingroup					
Enaliarctos	Absent	Small	No	V shape	Overlapping
Otariidae	Absent	Small	Yes	W shape	Overlapping
Desmatophocidae	Absent	Large	Yes	V shape	Interlocking
Phocidae	Absent	Large	Yes	V shape	Interlocking
Odobenidae	Absent	Large	Yes	Straight	Overlapping

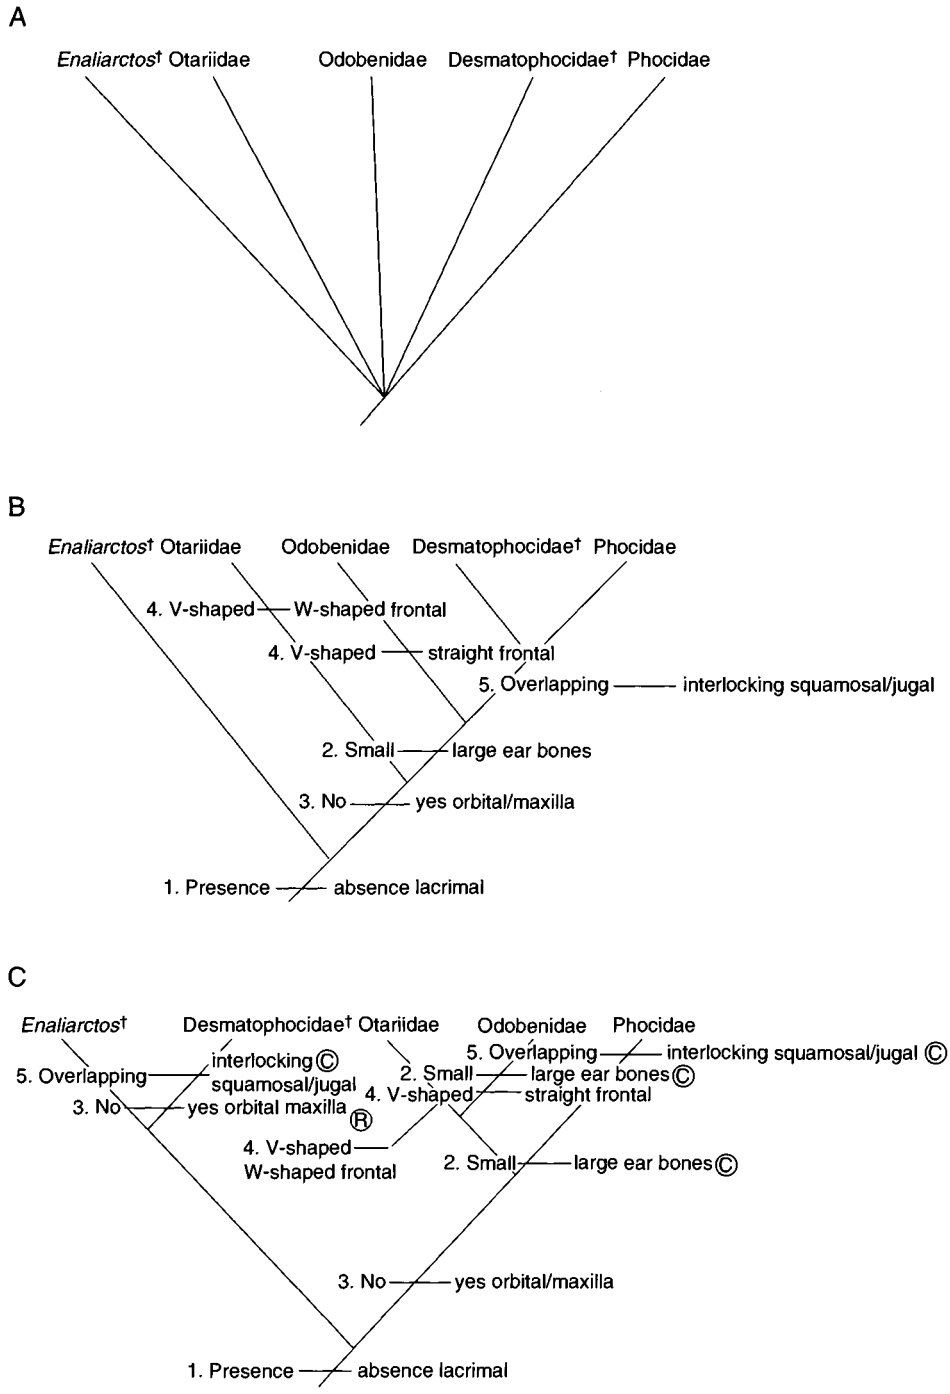

Figure 3 *Three possible cladograms (A–C) of relationships and character-state distributions for the ingroups listed in Table I. Convergences and reversal are denoted by a circled C and R, respectively.*

character No. 1, condition of the lacrimal bone, is considered, two character states are recognized: presence versus absence (or fusion of the lacrimal such that it does not contact the jugal). The outgroup (bears) possess a lacrimal bone condition, which is the ancestral state (Table 1). Ingroup taxa lack the lacrimal bone, which is the derived condition. Because this derived state unites pinnipedimorphs to the exclusion of bears, it is considered a synapomorphy.

A final step in phylogeny reconstruction is the construction of all possible cladograms by sequentially grouping taxa based

on the common possession of one or more shared derived character states (Fig. 3). An important aspect of phylogeny reconstruction is the principle of *parsimony*. The basic tenet of parsimony is that the cladogram that contains the fewest number of evolutionary steps, or changes between character states of a given character summed for all characters, is accepted as being the best estimate of phylogeny. In this example, Fig. 3B is the most parsimonious cladogram. Note that an alternative cladogram for the data set (Fig. 3C) showing different relationships among the five taxa requires nine characters state changes, three more than the most parsimonious cladogram (Fig. 3B).

The methods used to search for the most parsimonious tree depend on the size and complexity of the data matrix. These methods are available in several computer programs [e.g., PAUP (Swofford, 1998) and MacClade (Maddison and Maddison, 1992)]. The latter is particularly useful in assessing the evolution of characters. Systematists have become concerned about the relative accuracy of phylogenetic trees (i.e., how much confidence can be placed in a particular phylogenetic reconstruction). Various measures (e.g., tree length) and indices (e.g., consistency index, rescaled consistency index) have been devised to address this concern (reviewed by Swofford, 1998). Another approach that is often used to estimate the value of a particular cladogram with respect to data places confidence limits on the individual branches, a technique known as *bootstrapping*. Another concern stems from the realization that an increase in the size of data sets results in a greater chance of the analysis resulting in more than one equally parsimonious tree. A method of working with multiple trees involves the implementation of *consensus* trees that are useful in identifying the areas of agreement and conflict among competing trees. Perhaps the greatest influence on the accuracy of a cladogram is the number of taxa. When only a few taxa are used (e.g., exemplars of a group), or when only a small number are available, the accuracy of the phylogenetic reconstruction suffers. In summary, many factors should be considered in evaluating phylogenetic hypotheses, among the most important being taxonomic sampling and rigorous analysis, including the underlying assumptions of various methods.

III. Phylogenetic Classification

Taxonomy is the language of biology. One aspect of taxonomy is the classification of organisms that allows us to organize and communicate information about life's diversity. Phylogenetic systematists contend that classification should be based on phylogeny and should include only monophyletic groups. In contrast to monophyletic groups, a *paraphyletic* group (designated by quotation marks) is one that includes a common ancestor and some but not all of the descendants of that ancestor. An example of a paraphyletic taxon is the "Otarioidea," a group that includes walruses, otariid seals, and their extinct relatives to the exclusion of phocid seals (see Fig. 1). The recognition of paraphyletic taxa is to be avoided since by doing so we risk misinterpreting the evolutionary relationships of taxa and their classification. One result of the use of phylogenetic methodology is that traditionally accepted ranks (e.g., phylum, class, order, family, genus, and species) often do not correspond to new information about evolutionary relationships among taxa, thus rendering their classification misleading. One method is the elimination of rank altogether and the indication of relative rank by subordination as shown by indentation. An example, the classification of major lineages of pinnipediformphs, is shown in Fig. 4 based on the phylogeny in Fig. 2.

IV. Uses of a Phylogeny

Once a phylogenetic framework is produced, one of its most interesting uses is to elucidate questions that integrate evolution, behavior, and ecology. One technique used to facilitate such evolutionary studies is optimization or *mapping*. Once a cladogram is constructed, a feature or condition is selected to be examined in light of the phylogeny of the group. Examples using marine mammals include the evolution of body size in pinnipeds (Wyss, 1994), pinniped host–parasite associations (Hoberg, 1995), and the evolution of locomotor and feeding behavior in pinnipeds (Berta amd Adam, 2001), cetaceans (Thewissen and Fish, 1997), and sirenians (Domning, 2000). One of these studies, the evolution of locomotion among sirenians, is briefly reviewed here. A cladogram of relationships among sirenians was first established based on morphologic data. Next, using this phylogenetic framework, Domning (2000; Fig. 5) mapped locomotor characters onto the tree. Sirenians passed through three locomotor stages from a terrestrial quadrupedal ancestry. In the first stage exemplified by archaic sirenians, the prorastomids, swimming was accomplished by alternate thrusts of the hindlimbs. This was followed by a second stage seen in the extinct taxon *Protosiren* that employed dorsoventral spinal undulation and bilateral thrusts of the hindlimb in SWIMMING. In a final stage, seen in modern sea cows and manatees, sirenians have evolved into completely aquatic animals, swimming with the tail only.

Pinnipedimorpha (including *Enaliarctos* and all other pinnipeds)
Pinnipedia (fur seals, sea lions, seals, walruses and their extinct relatives)
Otariidae (fur seals and sea lions)
Phocomorpha (walruses, seals, and their extinct relatives)
Phocoidea (including *Allodesmus, Desmatophoca*, seals and walruses)
Phocidae (seals)
Odobenidae (walruses)

Teeth

NOBUYUKI MIYAZAKI
Otsuchi Marine Research Center, University of Tokyo, Japan

Teeth in mammals are generally confined to the margins of the upper and lower jaws and are placed in four groups: incisors (I), canines (C), premolars (PM), and molars (M). The dental formula for a typical mammal is written simply as I3/3, C1/1, PM4/4, M3/3 × 2 = 44. All teeth except the molars normally have a "milk" or deciduous set preceding the permanent ones. However, marine mammals, which are well adapted to water life, show various kinds of teeth in number and shape. Among marine mammals, teeth of cetaceans are highly specialized compared with pinnipeds and sirenians. In cetaceans, odontocetes have a wide variety in number and shape of teeth, whereas mysticetes are characterized by a complete absence of teeth. Most of odontocetes exhibit clear differences in tooth numbers and shapes from typical placental mammals. In some odontocetes, such as beaked whales, the pygmy sperm whale (*Kogia breviceps*), and the sperm whale (*Physeter macrocephalus*), there is a reduction in the number of teeth in the jaws. Odontocetes have nearly homodont or peg-like teeth. Thus, in odontocetes the total tooth number for each side of the jaw is simply combined here as a single number (Table I).

I. Cetacea

Mysticetes are characterized by a complete absence of teeth, although teeth may be found in the fetal stage. For feeding on planktonic or micronectonic crustaceans such as krills and/or small pelagic fish, they use a row of baleen plates that project ventrally from the outer edges of the roof of the mouth. Odontocetes differ from mysticetes in feeding principally on fish and/or squid. The diet of odontocetes might reflect on the morphology and number of teeth. In odontocetes, there is no deciduous dentition. The tooth consists of enamel, prenatal dentine, postnatal dentine, cementum, and pulp cavity. Most phocoenids have spatulate teeth and delphinids conical teeth.

TABLE I
Number of Teeth in the Upper/Lower Jaw on Each Side[a]

Cetacea	
Globicephala melas	8–13 / 15–18
G. macrorhynchus	7–8 / 7–8
Pseudorca crassidens	7–12 / 7–12
Lagenorhynchus obliquidens	23–26 / 23–26
L. obscurus	27–36 / 27–36
L. albirostris	22–28 / 22–28
L. acutus	30–40 / 30–40
L. australis	27–33 / 27–33
L. cruciger	26–35 / 27–35
Tursiops truncatus	18–26 / 18–26
Orcinus orca	10–12 / 10–12
Grampus griseus	0 / 2–7
Steno bredanensis	19–26 / 19–28
Sousa chinensis	30–35 / 31–34
S. plumbea	31–38 / 30–37
S. teuszii	27–30 / 27–31
Sotalia fluviatilis	25–36 / 25–36

TABLE I *(Continued)*

[a]From Ridgway and Harrison (1981, 1985, 1989, 1994) and Jefferson *et al.* (1993).

In most odontocetes, there is wide individual variation in tooth number. For example, in the sperm whale (*Physeter macrocephalus*) and the short-beaked common dolphin (*Delphinus delphis*), the total number of teeth may exhibit a 1.5-fold difference among individuals. Among members of the Delphinidae the number varies from 0/2 in Risso's dolphin (*Grampus griseus*) to 44–64/42–62 in the spinner dolphin (*Stenella longirostris*). The spinner dolphin shows a wide geographical difference in number. The average highest tooth count in the lower tooth row is 45–46 in Thailand and northern Australian series, while it is 51–53 in the Central and South Pacific, western Pacific, and Philippines.

The unerupted small teeth of sperm whales remain in the upper jaw during life, as well as the pygmy sperm whale and the dwarf sperm whale (*Kogia sima*), and all of the lower teeth are erupted around sexual maturity. In the sperm whale the number of teeth is 0 for erupted and about 10 for unerupted teeth in each side of the upper jaw and 17–29 in the lower jaw. Pelagic dolphins such as *Stenella* spp. and *Delphinus* spp. are wide ranging in the subtropical and tropical regions of the world and are opportunistic feeders. The pincer-like action of the jaws of these long-snouted forms allows fish to be trapped by the interlocking tips of the teeth when the jaw closes and water is forced out. However, some beaked whales, the narwhal (*Monodon monoceros*), and Risso's dolphin, which capture prey by suction feeding, have a relatively constant and small number of teeth.

Tooth morphology also differs among species (Fig. 1). Teeth of the beaked whales are of various shapes and at various positions in the lower jaw (Fig. 2). In males, one pair of teeth in the lower jaw is erupted at attainment of sexual maturity, whereas in females they remain unerupted during life. It has been suggested that the erupted teeth may function to guide prey in the mouth, but because females and immature males lack these teeth, it is more likely that they function in intraspecific fighting. In the beaked whales of the genus *Mesoplodon*, maxillary teeth are absent with some exceptions. Gray's beaked whale (*Mesoplodon grayi*) and Shepherd's beaked whale (*Tasmacetus shepherdi*) contain functional teeth in the upper jaw. Gray's beaked whales have a series of 17–22 erupted small teeth in the upper jaw; however, they are not rooted in the maxilla but rather in the soft tissue over it. Some specimens of Sowerby's beaked whale (*Mesoplodon bidens*) have vestigial teeth in both upper and lower jaws. Among beaked whales, the position and shape

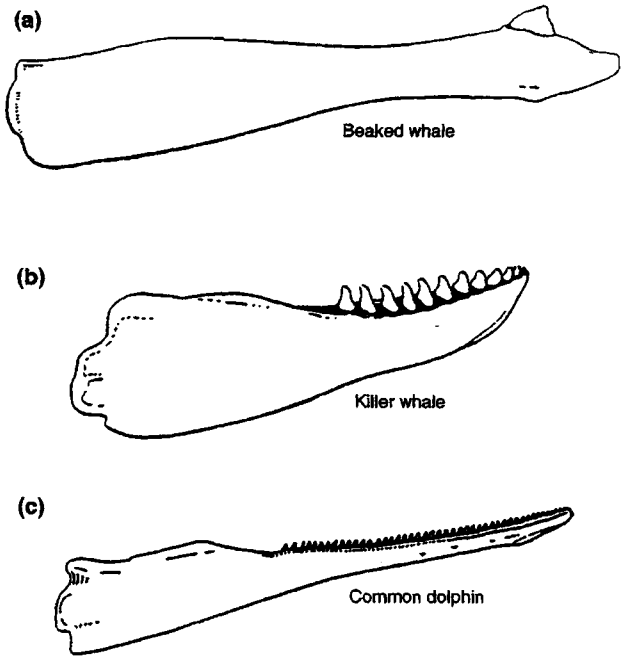

Figure 1 *Comparison of representative lower dentitions of odontocetes: (a) beaked whale (Ziphiidae), (b) killer whale* (Orcinus orca), *and (c) common dolphin* (Delphinus delphis) *(Slijper, 1979; Berta and Sumich, 1999).*

of the teeth in the mandibles of adult males are the most important key in identifying species of the genus *Mesoplodon*, although the shape of teeth changes with growth. In Cuvier's beaked whale (*Ziphius cavirostris*), which has one pair of teeth apically, some vestigial teeth are often found in the lower jaw.

The Amazon river dolphin (*Inia geoffrensis*) has 100–140 teeth, which are conical in the anterior half of each jaw but in the posterior have a lingual flange extending from the crown. Wrinkling of the enamel makes the teeth surface rugose. In the franciscana (*Pontoporia blainvillei*), the crown is slender, slightly compressed anteroposteriorly. The enamel is smooth. In the Indian river dolphin (*Platanista gangetica*), the lower teeth are much longer than the upper, and in young animals the anterior upper and lower teeth interlock, overlapping the sides of the jaw. Although narrow and sharp in young, the teeth become worn and flattened with age.

Sperm and beaked whales exhibit a number of adaptations for employing the tongue as a piston for sucking squid into the mouth. This suction-feeding strategy is characterized by a reduced number of teeth and a small gape to allow unobstructed entry of small prey, a ribbed palate to help hold slippery-bodied squid, and throat grooves to allow for expansion of the throat region. The suction-feeding mechanism in BEAKED WHALES involves distension of the floor of the mouth provided by throat grooves and retraction of the tongue by the styloglossus and hyoglossus muscles.

Teeth are used not only for feeding but also as a symbol of social status and/or aggressive display of adult males. Tooth marks of the adult male are often found on the ventral side of Baird's beaked whale (*Berardius bairdii*). In both sexes of Baird's beaked whale, the lower jaw typically bears four teeth, which are composed of a large triangular pair situated apically and a smaller peg-like pair posterior to a short diastema. The teeth erupt around the onset of sexual maturity in both sexes, with the apical pair projecting obliquely forward well beyond.

Among odontocetes, tusks of NARWHAL, which exceed 3 m in length and have prominent left-handed spiral ridges, are the most specialized teeth. The spiral of the tusk is sinistral (or left-handed) when viewed from the root. The tusk extends anteriorly from the head. The left anterior tooth usually erupts as a tusk only in males. However, male narwhals occasionally develop two tusks or may lack an erupted tusk, and females may develop a left tusk or both tusks. When present, the tusks of females are shorter and less robust than in males. The large disparity in size between male and female narwhals and the

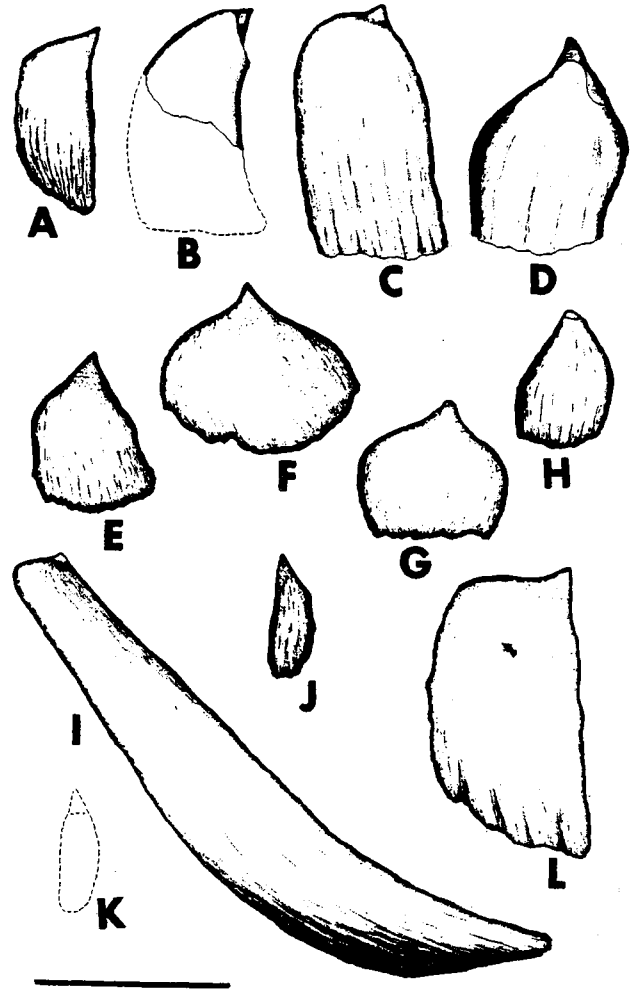

Figure 2 *Lateral views of right teeth of adult male* Mesoplodon: *(A)* M. bidens, *(B)* M. bowdoini, *(C)* M. carlhubbsi, *(D)* M. densirostris, *(E)* M. europaeus, *(F)* M. ginkgodens, *(G)* M. grayi, *(H)* M. hectori, *(I)* M. layardii, *(J)* M. mirus, *(K)* M. later attainment of sexual maturity in the male strongly suggest that the tusks are used in sexual display among males. It has been hypothesized that the tusk is used for the nonviolent assessment of social status on the basis of relative tusk size during frontal encounter, but evidence from head scarring and broken tusks indicates that adult males may indulge in aggressive displays that involve violent fighting.

II. Pinnipedia

Pinniped species have some reduction of teeth and milk dentition is less developed compared with typical mammals. The teeth posterior to the canines are little differentiated from one another and are referred to as postcanines (PC) or cheek teeth because molars are not clearly distinguished from premolars. Without the need for slicing or chewing while processing food (prey are swallowed whole), the cheek teeth of pinnipeds are typically homodont with a single pointed cusp for gripping slippery prey. Posterior cusps may also be present and are more frequent on posterior cheek teeth. A double-rooted condition of cheek teeth is the ancestral condition, apart from the first premolar, which is single rooted. The permanent incisors and canines normally have milk precursors, but of the postcanines, only the second, third, and fourth are preceded by milk teeth. As the permanent teeth erupt, the small alveoli gradually obliterate the alveoli of the milk teeth in the jaw.

In the WALRUS (*Odobenus rosmarus*), the formula for milk dentition is I3/3, C1/1, PC3/3 × 2 = 28. Milk teeth are shed shortly after birth, but not all of them are succeeded by permanent teeth. Most of the functional teeth erupt in the first and second years after birth. In the adult, the formula for functional dentition is I1/0, C1/1, PC3/3 × 2 = 18. All the teeth are simple conical crowns with a single root. The permanent upper canines erupt at about 4 months of age. They have persistently open pulp cavities and continue to grow throughout the life of the animal, although the tips are abraded constantly during feeding. The upper canine teeth develop into large "tusks" in both sexes. The tusks of males are larger, thicker, spaced farther apart at the base, and more divergent at the tips than those of females, and a single tusk may reach 1 m in length (35 cm is average) and weigh as much as 5.4 kg. Male walruses use their tusks mainly in dominance displays, females use them to defend themselves and their young, and they are occasionally used by both sexes to pull themselves onto ice floes. Tusks are not usually used in feeding, although rarely they are used to stab seal prey. The abrasion to the tips is the result of the tusks being scratched by sediment as an animal is searching for mollusks, its primary prey.

In Otariidae, the retention time of milk teeth depends on when the pups bite floating and other objects, but most of the milk teeth are shed by 4–5 months after birth, although there is some individual variation. Otariids have more teeth than phocids and both have more than the walrus (Table I). The permanent teeth of otariids are less diverse in morphology than those of phocids. The typical otariid dental formula is I3/2, C1/1, PC6/5, with some interspecific differences and individual variation.

Among Phocidae, phocines have incisors 3/2 (except for the hooded seal, *Cystophora cristata*, which has 2/1) and monachines have incisors 2/2 (except for the elephant seals, *Mirounga* spp., which have 2/1). In almost all phocids species the rest of the dental formula is C1/1, PC5/5. There is considerable variation in tooth shape and degree of cusp development (Fig. 3). Cheek teeth of the crabeater seal (*Lobodon carcinophaga*) and, to lesser extent, of the leopard seal (*Hydrurga leptonyx*) are highly modified with complex elongated cusps to trap and strain krill. Both crabeater and leopard seals are thought to suck krill into their open months by retracting their tongues and then forcing excess water out through the sieving cheek teeth. Leopard seals also possess well-developed canines for preying on penguins, other seabirds, and other pinnipeds.

III. Sirenia

The dugong (*Dugong dugon*) has a fixed dental formula of I2/3, C0/1, PM3/3, M3/3 with vertical replacement as in most other mammals. Dugong dentition is distinctly different from that of manatees, which lack incisors and have a different pattern of cheek tooth replacement. Two pairs of upper incisors are small and present in the juvenile dugong. Lower incisors and a canine are vestigial teeth. The deciduous (first) incisors are small, do not erupt, and are resorbed. In males, the deciduous incisors are lost around the time of tusk eruption, and their sockets disappear as the tusks expand. The tusks of males erupt at around 12 to 15 years of age and may be up to 15 cm in length with protrusion of a couple of centimeters. In females, small partially resorbed incisors may persist until the animal is about 30 years old. The permanent incisors (tusks) develop in both sexes but only erupt in males and some old females. In some old females the tusks erupt and wear, indicating that tusk eruption is not always diagnostic of the males. There are six cheek teeth (three premolars and three molars) in each jaw during the life of the dugong. These three premolars are erupted at birth and fall out because the roots of the anterior teeth are progressively resorbed. Their sockets then become occluded with bone. The molars progressively erupt during growth. The second and third molars continue to grow so that the occlusal area of the cheek teeth is maintained and increased even after the loss of anterior cheek teeth.

In the MANATEES (*Trichechus* spp.) there are usually five to seven functional teeth in the upper and the lower jaws. Cheek teeth are replaced from the rear and fall out, as anterior teeth wear from the excessive amount of sand and grit taken during feeding on plants. The total number of teeth per jaw is estimated at 20–30 during the life of an individual. Cheek teeth are brachyodont, or short crowned, and are enameled but lack cementum. There are two vestigial incisors in each jaw at birth, but they are later resorbed. It was thought that tooth replacement in the manatee occurs throughout the life of the individual, but there is evidence that this may not be the case. Teeth are replaced from the rear and, as anterior teeth wear they fall out. The increase in solid food intake after weaning, and hence more chewing, acts as a mechanical stimulus for the initiation and continuation of tooth row movement. Although it is sometimes incorrectly compared to elephants, this combination of horizontal movement with an appar-

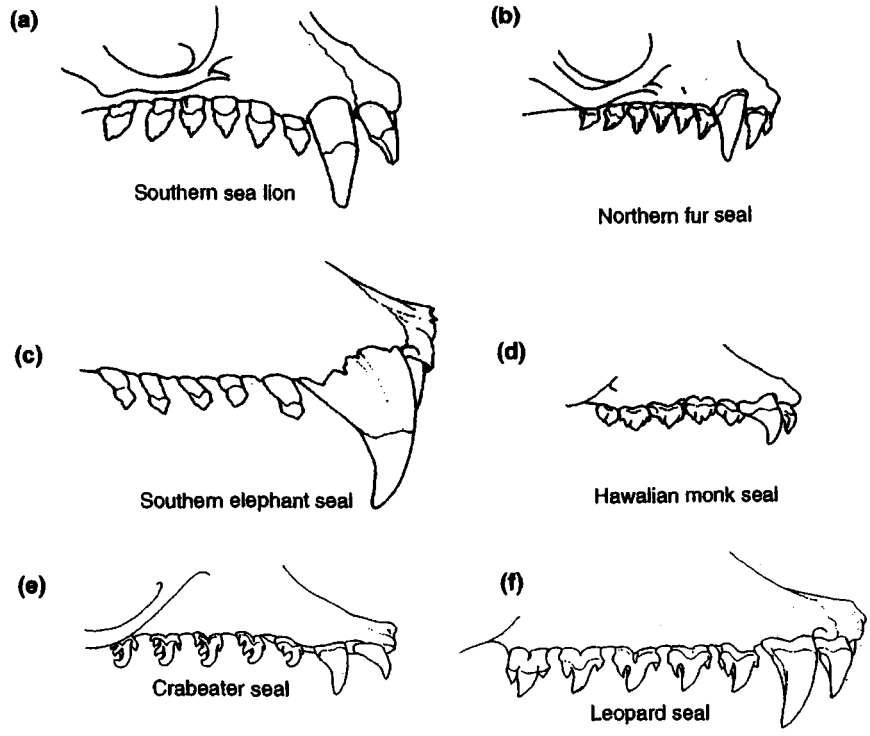

Figure 3 *Comparison of representative otariid (a and b) and phocid (c, d, e, and f) upper dentitions (King, 1964; Berta and Sumich, 1999): (a)* Otaria flavescens, *(b)* Callorhinus ursinus, *(c)* Mirounga leonina, *(d)* Monachus schauinslandi, *(e)* Lobodon carcinophaga, *and (f)* Hydrurga leptonyx.

ent limitless supply of supernumary (extra) molars is found in no other mammal, including the dugong.

IV. Age Determination of Marine Mammals

To understand the life history of aquatic animals, age determination is a fundamental factor. Techniques for age determination of animals vary widely among species and among investigators. One of more reliable methods involves determining an individual's age using teeth, mandibles, and ear bones. As an animal grows, incremental layers accumulate in the above hard tissues. These incremental growth layers, which are analogous to rings in tree trunks, are used for age determination of animals. Thus, counting these layers is now widely used to estimate ages of marine animals. Teeth typically are obtained from dead specimens and from captive or temporarily restrained individuals of all groups of marine mammals except mysticetes, in which growth layers in the large waxy ear plugs, as well as tympanic bullae and skull bones, have been used. Procedures for enhancing the visibility of growth increments usually include thinly slicing and polishing teeth and then etching or staining the polished surface to better resolve the growth layers. Each countable unit of repeating incremental growth layers contains at least one change in tissue density, hardness, or opacity and is referred to as a growth layer group (GLG). In most species examined so far, each GLG is thought to represent an annual increment. Useful methods for age determination by teeth are summarized as (1) preparation of unstained longitudinal thin section, (2) preparation of decalcified and stained longitudinal thin section, (3) etched preparation of the surface of the sanded half-tooth, (4) preparation of scanning electron microscopy, and (5) preparation of microradiography. The latter two methods are not convenient for mass preparation in a short time. The etched preparation of a longitudinally sectioned tooth is a good method for larger dolphins with larger teeth, and thin undecalcified sections are also useful if the longitudinal section is cut accurately or ground to include the largest possible longitudinal section of the pulp cavity. However, such material is suitable for dentinal counts only. Although the number of cemental growth layers is almost the same as the number of dentinal growth layers for young animals, the former exceeds the latter for old ones.

Cemental growth layer groups should be counted in very carefully prepared specimens of the decalcified and stained tooth. Preparation of the decalcified tooth in 5% formic acid for 24 hr and staining with Mayer's hematoxylin solution for about 30 min of a longitudinally thin section (10–20 μm) gives better results for small delphinid teeth.

Telemetry

ANDREW J. READ

Duke University Marine Laboratory, Beaufort, North Carolina

Telemetry is the process of obtaining data remotely by transmitting information from a marine mammal or by storing information for later retrieval. Telemetry includes a number of research approaches, from simple radio tags that allow researchers to relocate a tagged animal to complex data loggers that record data from multiple environmental sensors. Recent advances in this field have led to extraordinary insights into the behavior, ECOLOGY, and physiology of marine mammals. It is now possible to obtain data via satellite on the fine-scale behavior of marine mammals from the most remote regions of the world's oceans. It is also possible, for the first time, to record on videotape what a marine mammal sees as it swims through the water column. These advances allow researchers to investigate how marine mammals use their three-dimensional world and to identify and quantify important physical and biological aspects of their environments. To understand the way in which telemetry has changed our understanding of marine mammals, one need only consult some of the older references on the diving capabilities of marine mammals. These early studies relied almost entirely on anecdotal observations, such as observations of sperm whales (*Physeter macrocephalus*) tangled in submarine cables. Today, we have a rich understanding of the diving capabilities of marine mammals from direct observations made using telemetry. The field continues to develop rapidly, fueled by continuing advances in technology and miniaturization.

There are two primary approaches to collecting data with telemetry systems. In the first approach, a data logger is attached to a marine mammal, records data for a predetermined period, and then is recovered, allowing researchers to download the information stored in the package. In the second approach, information is transmitted from a marine mammal via radio or acoustic signals.

I. Recoverable Data Loggers

Data loggers record information from a variety of sensors that provide insight into a marine mammal's behavior, physiology, and environment. The earliest data loggers were simple time-depth recorders that used smoked glass discs rotating past recording needles attached to pressure transducers. These devices were developed in the 1960s by Gerald Kooyman to study the DIVING behavior of Weddell seals (*Leptonychotes weddellii*). To record time in these devices, Kooyman incorporated simple kitchen timers. This ingenuity is typical of the field of marine telemetry, which is too small to support much of its own commercial research and development. Instead, biologists have adopted, modified, and refined technology developed for other purposes.

Modern data loggers are sophisticated digital devices, capable of storing large quantities of information. Data are collected from one or more sensors that measure depth, water temperature, light intensity, or swimming velocity. The sampling interval is set by the researcher and may vary depending on the type of question being asked. The location of a tagged animal can be determined by several methods, but the most common approach is to record light levels and times of dawn and dusk and to back-calculate latitude and longitude after the logger is recovered. It is also possible to record physiological data, such as heart rate and body temperature. Researchers can even record feeding events by transmitting temperature changes in the stomach to external data loggers. To monitor feeding events, a small transmitter, equipped with a temperature sensor, is introduced into the stomach of an animal and transmits data to a data logger mounted on its external surface. Most prey are heterothermic, or cold-blooded, so when they are swallowed, the temperature of the stomach drops abruptly. Eventually the transmitter is passed or regurgitated.

Two recent developments with data loggers have yielded new insights into the BEHAVIOR of marine mammals. The first is the development of a recoverable logger capable of recording sound—in essence, recording the acoustic environment of the tagged animal. These loggers incorporate hydrophones and recording media such as digital audio recorders or miniature hard drives, as well as other sensor systems. In addition to the vocalizations of the animals themselves and the sound of nearby vessels, the loggers have provided unexpectedly rich data on swimming stroke and heart rate. These devices are being used

by researchers to study the effects of anthropogenic noise on the behavior of marine mammals.

The second advance in logger technology is the crittercam—a recoverable video recorder system. Developed by researchers from the National Geographic Society, crittercams provide a visual record of everything that a marine mammal sees (if aimed forward) or everything in the path of the animal (if aimed backward). Because humans are visual creatures, these video records provide researchers with powerful insights into the underwater lives of marine mammals.

Data loggers have several advantages over other types of telemetry systems. First, because data storage requires considerably less power than data transmission, fewer and/or smaller batteries are required. In turn, this means that recoverable loggers are generally smaller than transmitting tags. Second, the storage of large quantities of data is possible, particularly with modern digital technology. As noted later, transmitting systems limit the quantity of data that can be relayed from the animal to a receiver.

The primary disadvantage of these systems is the need to recover the data loggers to retrieve stored information. The use of data loggers in studies of pinnipeds is fairly straightforward because these animals haul out at predictable times and locations. Researchers studying elephant seals (*Mirounga* spp.), for example, are able to recover up to 95% of their loggers because of the strong fidelity of these animals to their rookeries. Using data loggers with cetaceans, however, is considerably more challenging, as researchers must first attach the package to a dolphin or whale and then recover the tag after it is jettisoned. One solution to these problems is to attach the loggers with suction cups, fired from a cross bow, and then to recover the buoyant packages after release by homing in on a radio signal emitted by a tag in the package. Several researchers have employed this technique with success, although the logistics of such field work are considerably more complex than the deployment and retrieval of data loggers on pinnipeds.

II. Transmitting Systems

Transmitting systems have also undergone a rapid development over the past several decades. The earliest transmitters were omnidirectional radio or acoustic transmitters that allowed researchers to relocate a tagged animal but did not provide information on its behavior or physiology. These simple systems have evolved into sophisticated systems in which large quantities of data can be recorded, compressed, and transmitted.

Some of the earliest radio transmitters used with marine mammals were developed by Bill Watkins and W. E. Schevill from the Woods Hole Oceanographic Institution. In the 1960s, these researchers developed implantable radio tags fired into the blubber of large whales. Similar tags are still used today to study the movements and behavior of BALEEN WHALES. Radio tags have also been attached to the dorsal fins of dolphins and porpoises or glued to the fur of pinnipeds by other researchers. When successful, these tags have allowed researchers to follow marine mammals at sea and gain insight into their behavior and short-term movements. This labor-intensive field work requires the use of directional receiving antennae to home in on the radio signal produced by the transmitter.

The utility of these simple transmitting systems is limited by several factors. First, because the high-frequency signals emitted by radio tags attenuate rapidly in salt water, it is possible to receive signals only when the transmitter is above the surface. This complicates the tracking of animals because only a few signals are heard at each surfacing. Acoustic signals propagate for much greater distances underwater but often overlap with the hearing range of marine mammals, limiting their applicability. Even under ideal circumstances, radio transmitters have effective ranges of only a few tens of kilometers, so researchers are forced to stay in close proximity to tagged animals. Finally, the large size and cumbersome design of many early radio tags created significant hydrodynamic drag and resulted in the premature detachment of the packages.

Today, researchers have a wide variety of transmitting systems available to them. The most significant advance has been the development of satellite-linked radio transmitters that allow biologists to track the movements and behavior of marine mammals from their offices. The principle underlying these systems is fairly straightforward. Each transmitter emits a stable radio signal to receivers aboard orbiting weather satellites. As a satellite moves across the horizon, the received frequency of the tag changes, due to the Doppler shift, allowing estimation of the position of the transmitter. Each transmission also includes the identity of the transmitter and any associated sensor data. Data are processed and relayed to the user by modem or e-mail. This technological advance obviates the need for researchers to track animals in the field.

Satellite-linked radio transmitters have been coupled with data logging systems to allow the collection of detailed behavioral or environmental data from marine mammals via satellite. This coupling of data logging and transmitting systems has proven to be very successful because it precludes the need to recover the logger package to obtain sensor data. Typical data collected by these systems include depth and swim speed, although in principle any sensor system can be employed.

The advantages of transmitting systems lie primarily in their ability to provide data in real time. Even satellite-linked transmitter systems can provide telemetry data within a few hours, allowing researchers to monitor the movements and behavior of animals in real time from their offices. Simplicity has its virtues, however, and many researchers continue to use conventional radio tags to assist in the relocation of tagged animals in the field. Spending many hours with a particular individual allows for the collection of fine-scale behavioral data. Although it is often possible to use natural features to identify a dolphin or whale, a simple radio tag can greatly facilitate the relocation of a particular individual in the field.

Satellite-linked data loggers are extremely powerful data acquisition systems, but they do have limitations. Their signals can be received only when the transmitter is above the surface and a satellite receiver is overhead. Energy for signal transmission is a significant limitation with current battery technology, although battery life may be conserved by using a salt-water switch, which suppresses transmissions when the tag is sub-

merged. In addition, because the current satellite system limits each transmission to 256 bits, algorithms are required to compress complex data, such as records of individual dive profiles, prior to transmission.

III. Biological Insights

Advances in the field of telemetry have revolutionized our view of marine mammals. As terrestrial observers, we are limited in our ability to study marine mammals and, in the past, have been limited to collecting data from animals at the surface or ashore. While at sea, most marine mammals spend more than 90% of the time submerged, often in remote or harsh environments in which field research is difficult or impossible. Telemetry offers the potential to peer into the lives of whales, dolphins, and seals as they go about their daily activities of FEEDING, finding mates, and avoiding PREDATORS. For the first time, we can ask how a Weddell seal hunts for food under the Antarctic ice, how an elephant seal makes such long dives, or where blue whales go in the winter months. The insights provided by this technology will continue to challenge our thinking about these animals, particularly as new technological developments improve our ability to collect data at sea.

ELEPHANT SEALS have proven to be particularly amenable to study with telemetry. These are large animals that haul out to breed and molt at predictable times and locations but which spend the majority of the year far from shore. Thus it is possible to equip individual elephant seals with fairly large telemetry packages and be confident that most packages will be recovered. Researchers in both hemispheres have equipped a large number of elephant seals with recoverable data loggers and, more recently, satellite-linked data loggers. From this research, we now know that elephant seals in the North Pacific make two long-distance feeding migrations each year, one after breeding and the second after the molt. For example, adult male elephant seals travel from central California to the Gulf of Alaska on each migration, a distance of more than 10,000 km in each round trip. Individuals appear to return to the same feeding area each year and, once on the feeding grounds, forage almost continuously. While feeding, individual elephant seals dive repeatedly, spending more than 90% of their time at sea submerged, and sometimes diving to depths of more than 1500 m. Such behavior is consistent with what we know of the diet of these animals; elephant seals feed primarily on mesopelagic squid found at depths of 200 to 1000 m. These prolonged and continuous dives have raised many physiological questions, particularly with regard to the oxygen storage capacity of these animals (see later). The prodigious diving behavior of elephant seals has led some biologists to refer to them as mesopelagic mammals.

Elephant seals are not alone in possessing an impressive diving capacity. Sperm whales have been tracked using telemetry to depths of more than 2000 m during dives that may last for more than an hour. Beaked whales (Ziphiidae) are also capable of long, deep dives. Northern bottlenose whales (*Hyperoodon ampullatus*), for example, equipped with time-depth recorders attached with suction cups, have made dives to 1500 m and for over an hour in duration. Studies using satellite-linked data loggers attached to smaller whales, such as belugas (*Delphinapterus leucas*) and narwhals (*Monodon monoceros*), indicate that these species are also capable of prolonged, deep dives under the Arctic ice.

Studies with crittercams have provided dramatic findings regarding the behavior of marine mammals. Weddell seals have been videotaped flushing prey from crevices in the ice by blowing bubbles, and researchers have watched Hawaiian monk seals (*Monachus schauinslandi*) sleep and forage on the sea floor. This type of research has particular relevance to conservation because it is believed that monk seals may be endangered, in part, due to conflicts with commercial fisheries. Documenting the availability of prey and the success rate of capture attempts allows us to test such ideas directly for the first time. Backward-mounted crittercams have been used to study the diving behavior of a variety of marine mammals and, in particular, to investigate how whales and seals can make such long dives without exceeding their aerobic capacities. It now appears, for example, that elephant seals and other marine mammals conserve oxygen by gliding extensively during descent. These animals take advantage of the changes in buoyancy brought about by increased pressure at depth and can descend effectively with little extra expenditure of energy or oxygen.

IV. Future Developments

It is difficult to anticipate what surprises the field of telemetry has in store, but it is clear that these techniques will be an integral component of the toolbox of future marine mammal researchers. In particular, it is likely that more sensors will be developed to take advantage of the success of recoverable and satellite-linked data loggers. New sensors may monitor physiological parameters, such as blood oxygen concentration and blubber thickness. Miniaturization and refinement of the crittercam system will allow researchers to ask how deep-diving species, such as elephant seals and sperm whales, find and capture prey at depth. Interest has been expressed in using marine mammals as autonomous oceanographic data collection vehicles. A sample of elephant seals equipped with sensors measuring temperature, salinity, and depth could, for example, provide considerable information on the oceanography of the Southern Ocean. Marine mammals are adept at exploiting fine-scale oceanographic features that concentrate prey, such as frontal systems, and animals instrumented with appropriate sensors could provide considerable information about the location and dynamics of such processes.

New advances in digital technology will undoubtedly result in substantial improvements in our ability to store, transmit, and receive data. Future readers will no doubt find our current suite of data loggers and satellite-based telemetry systems quaint and outdated. Current advances in wireless technology hold great promise for our ability to telemeter data from marine mammals because many current applications in acoustic and video telemetry are limited by bandwidth: the amount of information that can be transmitted from the animal to a receiver. New low-orbit satellite systems could improve our ability to collect more data from a larger sample of animals. So, too, could a network

of autonomous underwater data collection systems, similar to those being developed for oceanographic and military purposes, facilitate the collection of data using acoustic telemetry.

Finally, current research efforts are developing attachment techniques that are less invasive and easier to employ, particularly with dolphins, porpoises, and whales. The use of suction cups to attach data loggers to whales for short periods is a good example of this type of innovation. With the advent of improved technology and smaller, more powerful batteries, the size of telemetry packages will also decrease. This will allow the application of this technology to a wider variety of marine mammal species and for longer periods than has been possible to date. The field of telemetry holds great promise to reveal new and exciting insights into the lives of marine mammals.

Territorial Behavior

Edward H. Miller
Memorial University, St. John's, Newfoundland, Canada

Territory and *territoriality* widely refer to the exclusive use of space by individuals or groups, entailing both spatial defense and advertisement. Such terms have been applied to diverse animal species (e.g., octopuses, insects, primates) and functions (e.g., nesting, mate attraction, feeding) over a broad range of scales in space (millimeters to kilometers) and time (seconds to years). Such broad ranges of biological forms and functions cannot be encompassed by a single definition. Definitions that apply to selected taxonomic groups or functions of interest and over scales of space and time relevant for those groups or functions are best.

In this article, "territoriality" and "territorial behavior" refer to behavior associated with obtaining, defending, or advertising occupancy of space. Of course when two animals interact agonistically, they always do so within a spatial framework, but social interactions by themselves do not constitute territorial behavior. "Territoriality" connotes something other than just behavior relative to the interacting animals themselves or to their arbitrary spatial positions, such as (1) specific spaces relative to other individuals or to the external physical environment or (2) particular spatial features (e.g., a haul-out ledge). Nevertheless it is usually impossible to draw a strict distinction between defense of a space and resources within that space for all situations because species (or individuals, age classes, or social classes) that are usually viewed as "nonterritorial" like walruses (*Odobenus rosmarus*) or elephant seals (*Mirounga* spp.) exhibit territorial-like behavior in some settings, and vice versa for "territorial" species like fur seals and sea lions (Otariidae; "otariid" hereafter). Therefore, in this article the application of the definition given earlier is broad.

Territorial size, clarity and constancy of territorial boundaries, the medium in which territories occur, and functions of territories are interwoven. Cetaceans, sirenians, and polar bears (*Ursus maritimus*) exhibit little behavior suggesting the exclusive use of space defended or advertised by individuals or groups, but territorial behavior is clearly expressed in sea otters (*Enhydra lutris*) and most pinnipeds.

I. Development of Territorial Behavior

Sexual differences in behavior appear early in life in otariids. Male pups are more aggressive than females and engage in play fighting and boundary displays (Section V) within the first few weeks of life. Young otariid males of all ages engage in such behavior commonly in their interactions with one another, both inside and outside the breeding season. Juvenile and subadult walruses (including calves), recently weaned elephant seals, and juvenile and subadult harbor (*Phoca vitulina*) and gray (*Halichoerus grypus*) seals also show sexual differences in social behavior, with males spending more time play fighting with one another.

Territorial males of most otariid species appear to try to keep females on their territories by herding (Section V). Herding behavior appears early in life, and male pups preferentially direct this behavior toward female pups (e.g., Australasian fur seal, *Arctocephalus forsteri*). Herding is also expressed by nonterritorial males during the breeding season, e.g., when they encounter females moving toward or away from breeding aggregations. In all otariid species, numbers of nonterritorial males (including subadults) may rush simultaneously into ("raid") breeding aggregations and herd or interact with females in various ways before they are chased away by territorial males [raiding male

South American sea lions (*Otaria flavescens*) may achieve some direct reproductive benefits]. In species that frequent the colony site year-round (e.g., Australasian fur seal), juvenile and subadult males herd pups and young juveniles occasionally at various times outside the breeding season. An extreme form of this behavior occurs in the South American sea lion, in which nonterritorial males frequenty carry pups away in their mouths following raids on breeding sites. They carry the pups into the ocean (where they may drown) and then to nonbreeding areas where the males herd and mount them, sometimes over several days; pups usually die.

II. Territorial Functions

Nonbreeding pinnipeds engage in many agonistic social interactions in disputes over resting places at haul-out and breeding colony sites. Nonbreeding individuals may also favor and defend particular sites during the breeding season (e.g., otariids, harbor seals). Despite their relatively minor costs and benefits, such airborne interactions constitute territorial behavior in the sense used in this article and employ similar motor patterns to those used in better known and more dramatic examples of territoriality by breeding animals. In otariids, breeding females compete with one another for favored or habitual sites for resting or for nursing the young, and older pups similarly interact agonistically with one another or displace younger pups from favored rest sites.

The best known and most dramatic forms of territoriality in marine mammals are shown by breeding adult males. Male sea otters, otariids, and some seals (Phocidae; "phocid" hereafter) establish territories seasonally where females give birth and enter estrus, or to attract estrous females that have given birth. Sometimes territoriality by male pinnipeds is expressed only after females haul out at a breeding site [e.g., Hooker's sea lion (*Phocarctos hookeri*), gray seal], and males may also change locations facultatively in response to female movements, attend and defend isolated lone females, or even defend female carcasses (Fig. 1). However, the ultimate explanation for male territoriality is to obtain access to estrous females, thereby increasing male reproductive success.

III. Territoriality in Space

Discrete, clearly defined territories are most apparent on small temporal scales, in situations of crowding, in species that have good locomotory abilities so they can efficiently patrol or defend their territories, or where environmental features (e.g., topographical irregularities) occur that can be used by the animals to demarcate territories. Such conditions rarely occur in the lives of cetaceans (especially open-ocean species) so territoriality is rare or nonexistent in that group. RIVER DOLPHINS, with their spatially restricted distributions, or species that feed on concentrated prey that are sedentary or spatially predictable may be exceptions. In Scotland's Moray Firth, year-round resident common BOTTLENOSE DOLPHINS (*Tursiops truncatus*) may be territorial and exclude seasonal (winter) conspecific visitors from deep waters, which are most favorable for feeding.

Most species of otariids breed on crowded colony sites and hold small territories; territories of male Hooker's sea lions are often no more than 3 m in diameter, for example (about 30 m^2 in area), and some northern fur seals (*Callorhinus ursinus*) hold territories that are little larger in diameter than a male's body length (Fig. 2). Larger territories occur in related species (e.g., about 200 m^2 in male Steller sea lions, *Eumetopias jubatus*). Small aquatic territories are held by some male Juan Fernández fur seals (*Arctocephalus philippii*) adjacent to breeding aggregations, and walruses hold small aquatic territories adjacent to mixed herds on ice. In general, however, aquatic territories are large: >100 m in length in some male Weddell seals (*Leptonychotes weddellii*), up to 1 km across in male sea otters, and up to 10 km across in some male harbor seals; aquatic territories are commonly not contiguous (Fig. 3).

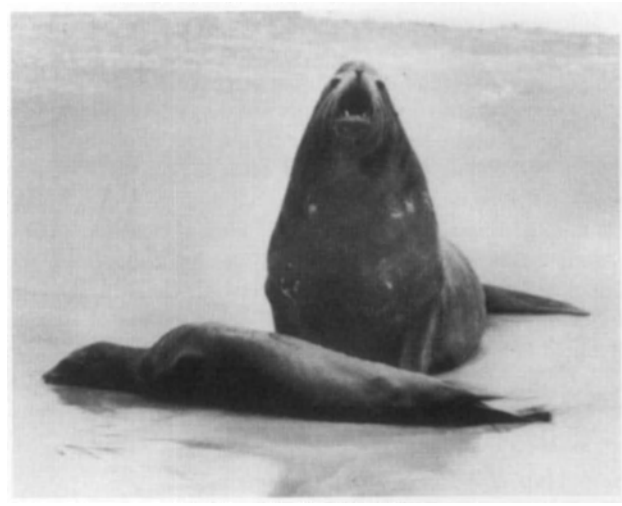

Figure 1 *Defense of space and of females is connected intimately in male marine mammals: adult male California sea lion defending carcass of female. From Peterson and Bartholomew (1967).*

Phocids are specialized for aquatic locomotion, so their locomotion on land is slow and energetically costly. Unsurprisingly, territories in land-breeding populations of gray seals exhibit extensive overlap (Fig. 4). The poor locomotory abilities and large size of the two species of elephant seals usually preclude territoriality, although in small confined areas (e.g., coves) the defense of space and of females amounts to the same thing.

Rocks, fracture lines, and other natural features often enable precise delimitation of otariid territories. If such features are present, then parts or all of a territory's boundaries can be discrete. Territories that are partly or completely on featureless terrain (e.g., sandy beaches) cannot be clearly delimited by territory holders, so shifts in size, shape, and even location are common. Aquatic territories may include or be adjacent to prominent geological features or landforms. In species that breed in association with ice, underwater features of ice, or fractures or leads in ice, may be important in determining territorial density, size, or shape (Fig. 3A). In the walrus, male territories are established in the water adjacent to mixed herds on ice (Fig. 5). The ice may be stable land-fast ice (e.g., parts of Canada's arctic archipelago) or unstable drifting pack ice (e.g., Bering Sea). Walrus territories are ill defined and variable due to variability in ice and herd size and dispersion.

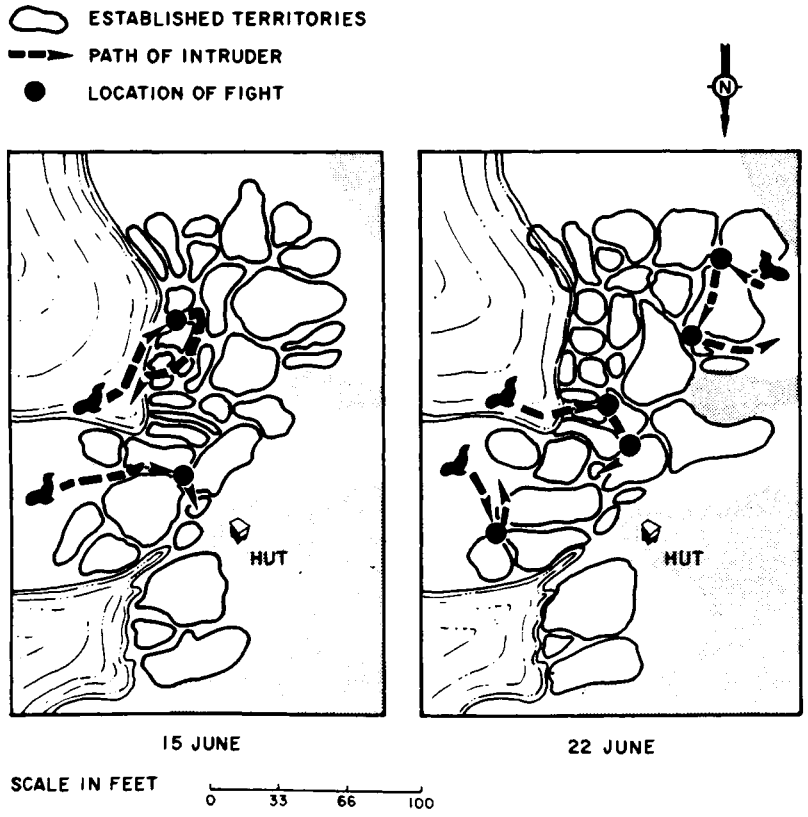

Figure 2 *Small, well-defined breeding territories occur in some species (northern fur seal). Territories are shown as slightly separated for clarity. Routes of entry into the existing territorial structure by males that obtained or failed to obtain territories are shown. From Peterson (1968).*

IV. Territoriality in Time

In otariids, size and shape of territories in shoreline locations are often influenced by the tide. Shoreline territories may alternately be above and partly under water and may be temporarily abandoned at high water levels (e.g., high tides, storms). Inland territories, especially those that lack pools in which males can cool themselves, may be abandoned in the heat of the day [e.g., Afro-Australian fur seal (*Arctocephalus pusillus*), Juan Fernández fur seal]. Walrus territories change in size, shape, and dispersion due to ice movements, amalgamation, and breakup.

Absence of females from their territories sometimes leads to territorial desertion by male otariids, but more commonly males attempt to acquire a new territory where females are present. In Hooker's sea lion, males establish territories several times during the breeding season in response to movement of the female aggregation down the beach. Southern sea lion males defend conventional territories (i.e., defense of space) early in the breeding season but gradually change to defense of females as the season progresses.

Territories of most or all otariids are most clearly defined at the peak of breeding, when territorial density is highest and territorial size is smallest (Figs. 2 and 6). Male otariids habituate to neighboring males and engage in fewer and less aggressive interactions with neighbors over time. A similar effect even occurs between males that held neighboring territories in the previous year (e.g., Steller sea lion). On Sable Island, Nova Scotia, some male gray seals abandon their territories and then establish new ones on the island some distance away (up to several kilometers) within the same breeding season; smaller scale changes within seasons also occur (Fig. 4).

Long-term fidelity to territorial locations has two components. First, there is a tendency for males to return to breed near the site of their birth (philopatry). Second, males exhibit site fidelity by tending to return in successive years to where they first established a territory. Both forms of site fidelity are known in otariids and terrestrially breeding phocids (elephant seals, gray seals). Site fidelity is especially strong in otariids; for example, one male Antarctic fur seal (*Arctocephalus gazella*) returned to within 1 m^2 of previous territorial locations over seven successive breeding seasons. Males exhibit breeding-site fidelity even in phocids that breed in association with fairly stable land-fast ice [e.g., ring seal (*Pusa hispida*), Weddell seal]. In contrast, some individual male gray seals in eastern Canada have been observed in different breeding seasons at terrestrial breeding sites and at sites where breeding takes place on ice. Male sea OTTERS hold territories in the same location for up to seven successive years. The combination of philopatry with general site fidelity suggests that kin may breed in close proximity to one another in otariids, gray seals,

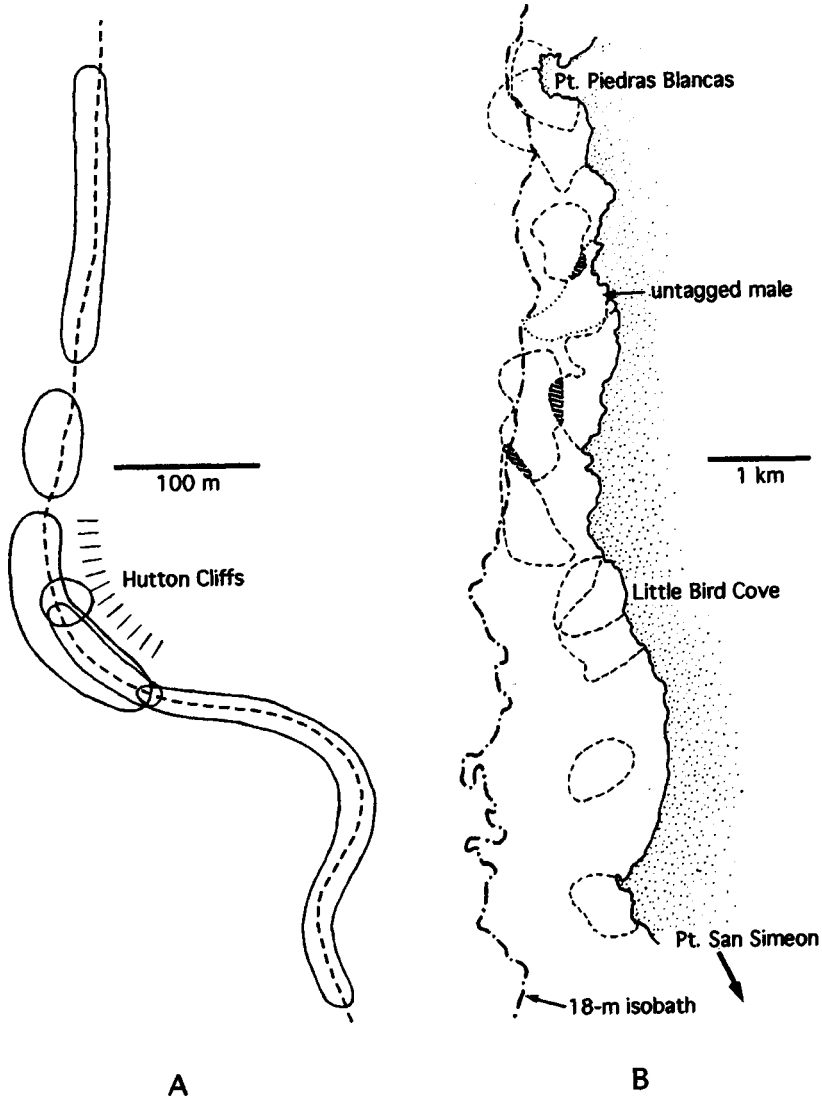

Figure 3 *Aquatic territories are typically large and overlap, but environmental features are important: Weddell seal (A) and sea otter (B). Six territories are outlined in A; the dashed line in A indicates a tidal crack in the ice on which territories were centered (the two small territories by the Hutton Cliffs were less well documented than the others). Eleven territories (10 of tagged males) are shown in B (note placement relative to water depth); overlap of concurrently held territories is indicated by hatching. From Kaufman* et al. *(1975) and Jameson (1989).*

and some other species. Behavioral effects of this possibility are not documented, but a detailed study of northern fur seals demonstrated that territorial males were careful to not injure pups (by stepping on them, for example)—pups that were sired in the previous year and therefore may have been the offspring of those males.

V. Obtaining, Defending, and Advertising Territories

Dramatic and potentially injurious fights between males occur in all territorial species, particularly when new males attempt to establish themselves. Because severe injuries or (rarely) death can result, fighting is undertaken only in specific circumstances; instead, most interactions between competing or neighboring males involve rich optical, acoustic, tactile, or chemical displays. In the northern fur seal, for example, only about 1% of encounters between territorial males involve actual fights.

The distinctive appearance of adult male otariids is communicatively important in the context of territoriality. For example, in contrast to females or young males, adult male California sea lions (*Zalophus californianus*) are much darker than

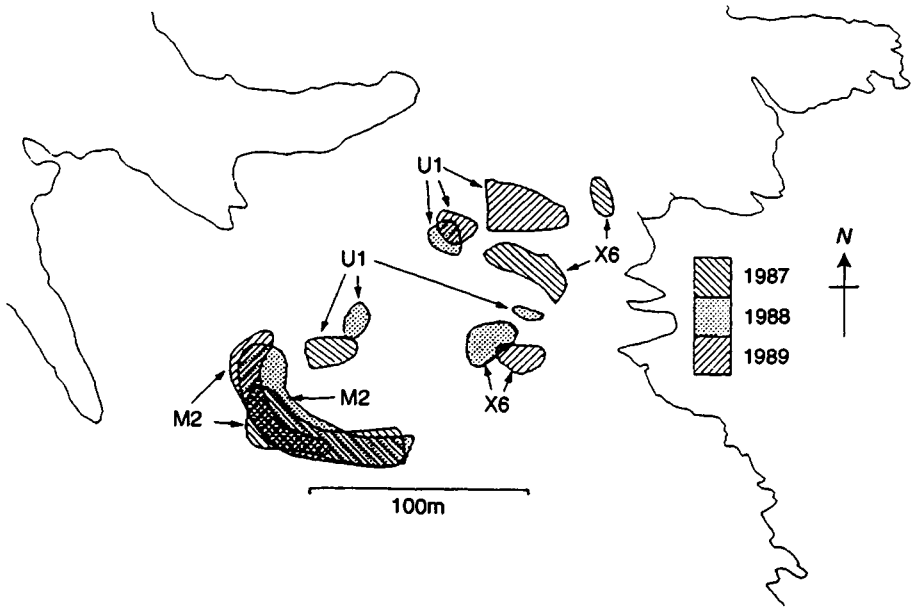

Figure 4 *Movements within and site fidelity between years are important in spacing systems of most or all territorial marine mammals: territorial male gray seals on North Rona, Scotland. From Twiss* et al. *(1994).*

females or young males, and adult male South American sea lions have distinctive manes. Some of the many optical displays of otariids are relatively passive and undirected (e.g., a distinctive nose-up upright resting posture). Most optical displays are directed toward specific individuals and involve movements, such as distinctive head-and-neck swinging LOCOMOTION, or rapid and complex sequences of motor patterns, including feints, oblique stares, sprawls, and facial expressions, in displays between neighbors across territorial boundaries (Fig. 7). Elephant seals and gray seals have specialized facial features used in displays over various distances (Fig. 8). In underwater communication, optical displays cannot effectively employ fine features like facial expressions so must rely on general patterns of pelage or on whole body movements or postures.

Acoustic displays can travel long distances and are energetically inexpensive to produce, so unsurprisingly are important in territorial displays of almost all marine mammal species. Not all such displays are vocal. Male sea otters patrol their territory while SWIMMING on their backs and kicking vigorously, thereby generating loud splashing sounds (this display probably represents

Figure 5 *Walruses hold small, dynamic aquatic territories adjacent to mixed herds on ice: territorial male (in water) adjacent to mixed herd in central Canadian arctic. From Sjare and Stirling (1996).*

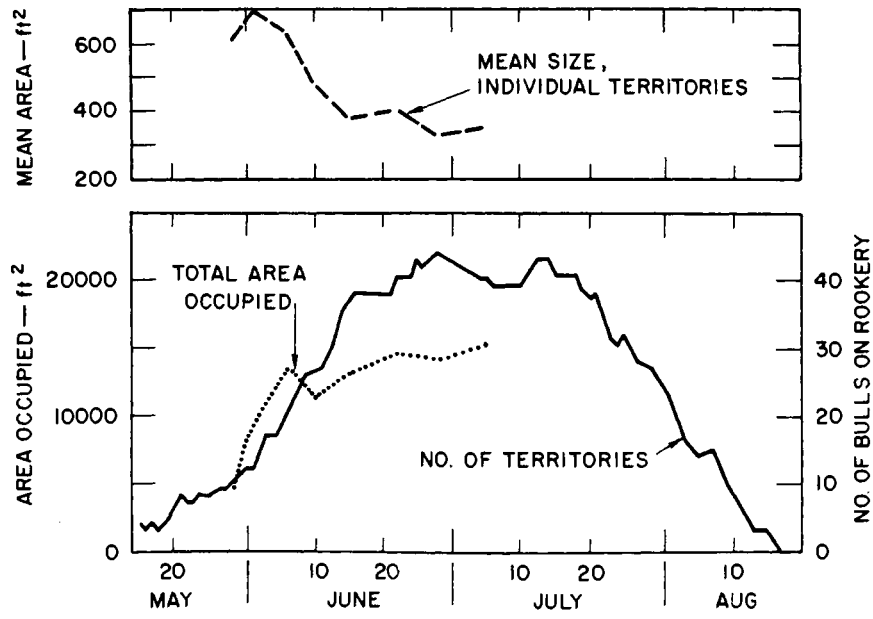

Figure 6 *Territorial size is smallest and defined most clearly in the peak of breeding: seasonal trends in territorial size in the northern fur seal. From Peterson (1968).*

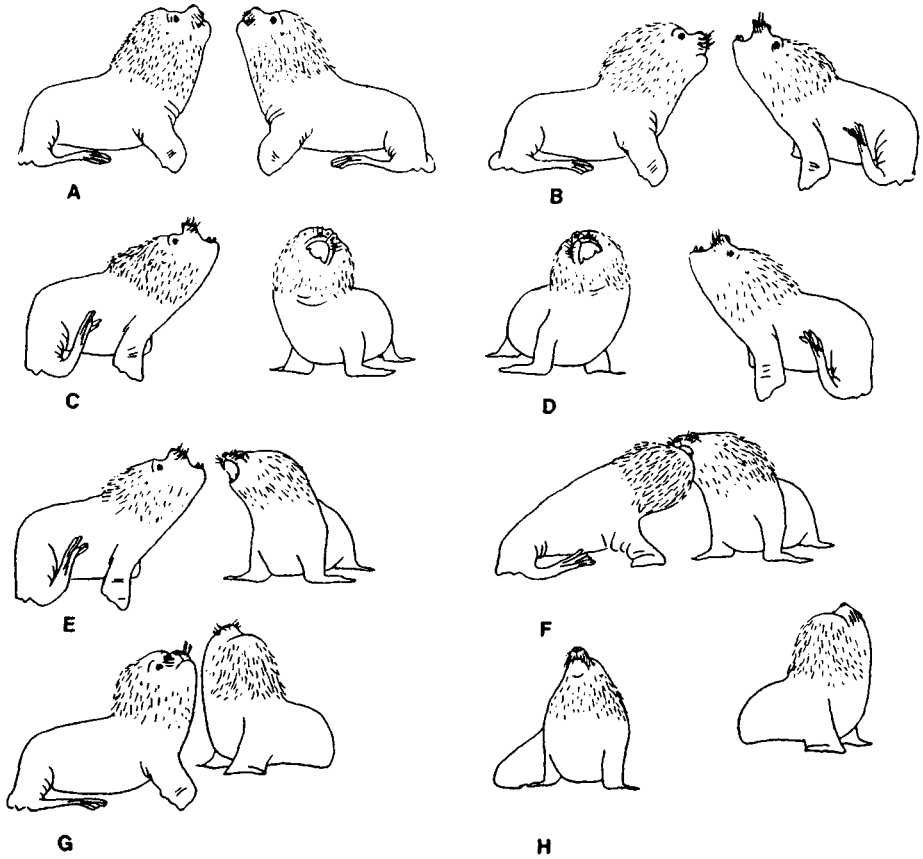

Figure 7 *Complex sequences of motor patterns typify short-range communication between territorial male marine mammals: behavioral sequence (A–H) in representative "boundary display" between male South American sea lions. From Campagna and Le Boeuf (1988).*

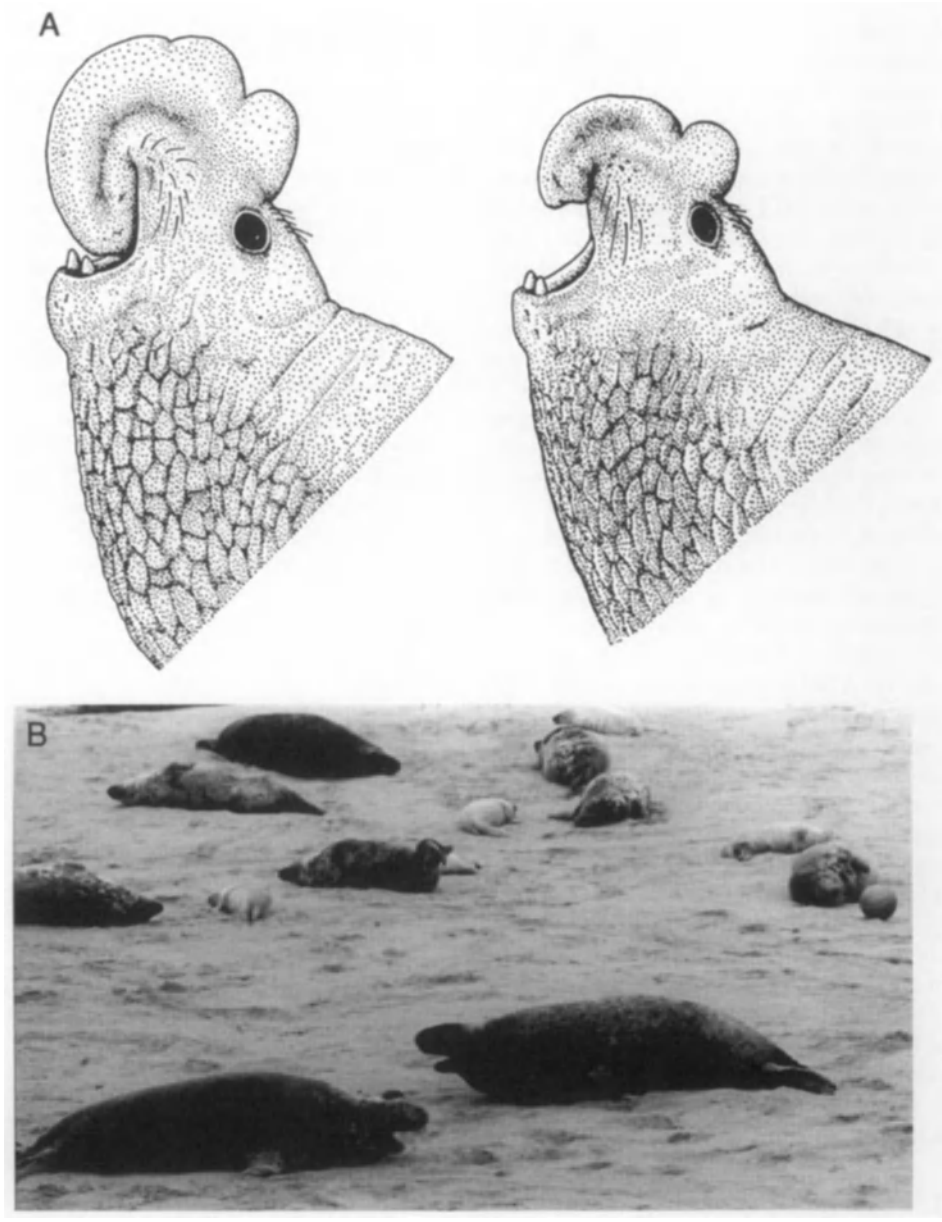

Figure 8 *General appearance and special structures are important aspects of displays between territorial marine mammals: (A) profiles of adult male northern (left) and southern (right) elephant seals* (Mirounga leonina) *with nasal hoods expanded (used in various displays) (from Briggs and Morejohn, 1976) and (B) adult male gray seals (in foreground) in antiparallel display on a breeding colony (Sable Island, Nova Scotia) (from Boness, 1979).*

ritualized swimming). In otariids and elephant seals, loud airborne distinctive vocalizations are given by breeding males. Underwater "songs" are well known in walruses and phocids, including Weddell and bearded seals (*Erignathus barbatus*). Loud sounds are probably designed to signal to a range of listeners (nonterritorial adult or subadult males, other territorial males, females), although in otariids they generally have been interpreted as a communication of "threat" among territorial adult males. Numerous medium- or short-range vocalizations are also given by territorial males; they are often directed toward other males, but are audible hence informative to all nearby animals. There are many unanswered questions about acoustic communication in both territorial and nonterritorial marine mammals; e.g., why do male sea otters and polar bears lack loud vocalizations for long-distance advertisement and why are male Hooker's sea lions, gray seals, and monk seals (*Monachus* spp.) virtually silent?

Chemical COMMUNICATION is probably important in all territorial species of marine mammals although is virtually unstudied. Facial glands are unknown in sea otters but the species

has well-developed anatomical (neural) characteristics for olfaction, and individuals often actively smell the air. Glands on the face (many associated with facial vibrissae) occur in otariids, walruses, and phocids and are known to vary seasonally in size and secretory activity in some species. Male otariids emit distinctive odors during boundary displays between neighbors, perhaps from the oral cavity, and have distinctive body odors during the breeding season, but the anatomical source and functions of the smell are unknown. Breeding male ringed seals hold underwater (and underice) territories that are near but do not overlap with areas used by breeding females. During the breeding season, adult males of this species acquire a strong odor, which is the origin of terms like "tiggak" ("stinker") among Inuit and "gasoline seal" among trappers. Male ringed seals may actively deposit secretions from facial glands on entrances to their breathing holes and subnivean ("below snow") resting lairs, and within the latter.

The roles of taste or use of the vomeronasal organ (VNO) are unknown, but otariids commonly exhibit slow, repeated tongue extrusion following agonistic displays (e.g., boundary displays or fights involving males; females, juveniles, and even pups also express the behavior), suggestive of behavior of other mammals that are known to use the VNO in chemical communication (at the very least, tongue extrusion is a conspicuous optical signal and likely has become ritualized as an optical display).

Tactile communication is also important but is essentially unstudied in marine mammals. Breeding males of all species engage physically and contact one another extensively in biting, wrestling, or pushing. Male sea otters often try to bite the opponent's penis, and fractured BACULA (penis bones) of mature males are relatively common in the species. In phocid species that fight aquatically, the rear flippers (necessary for aquatic locomotion) are bitten and injured frequently in fights; walruses use the tusks in physical contests in which males face each other, mainly at or just below the water surface. Physical contests in otariids, walruses, elephant seals, and gray seals on land take place with the animals facing each other, so most pushing, striking, biting, and so on involve anterior body parts.

VI. Costs of Territoriality

Competing for and holding territories are highly competitive and entail risks and costs. In all marine mammal species, physical and behavioral maturation in males is a slow process and differs from females. Males typically attain physiological sexual maturity years before they begin to compete for territorial status because they are neither physically large nor behaviorally experienced enough to effectively obtain and maintain territories.

Costs and risks of competition for territorial status are partly energetic but include dangers of suffering severe physical injury (the relative importance of these factors varies across species). Energetic considerations increase in importance after territorial status is achieved. Energetic costs are borne through advertisement and display, fights, herding, patrolling, alertness, and so on. Males reduce their food intake (e.g., harbor seals) or fast completely (e.g., otariids, elephant seals, gray seals) when they are territorial. The combined effects of reduced food intake or fasting plus high energetic expenditure are large. On average, territorial male northern fur seals fast and do not drink for about a month (maximum 87 days) and decline by about a third in body mass over that time. This loss in body mass is equivalent to about 0.7% of initial body mass per day, a level exceeded by several other species: Antarctic fur seals (0.8%), gray seals (0.9%), and the aquatically territorial Weddell seal (0.8%). The large northern elephant seal (*Mirounga angustirostris*; ca. 1700 kg) and the harbor seal, in which breeding males do not fast completely, lose less (about 0.4% per day), but overall costs are high in all species and are extreme in some individuals (one territorial male harbor seal lost 30% of his initial body mass).

Territorial male marine mammals must balance the need to economize energetically with the need to be vigilant, defend their territories, and effectively advertise territorial occupancy and their own physical attributes. Studies of time–activity budgets have revealed that territorial males spend much time at rest and little time in the most dangerous or energy-demanding activities such as fights.

Mortality rates of males are similar to those of females until the age of social maturity is attained. Beginning then, mortality rate of territorial males surpass those of females, sometimes by several times.

Tethytheria

PASCAL TASSY
National Museum of Natural History, Paris, France

The name Tethytheria was coined by the American paleontologist Malcolm C. McKenna in 1975 to group extant sirenians (order Sirenia) and elephants (order Proboscidea) and extinct desmostylians (order Desmostylia). Tethytheria means "beast of the Tethys," with the Tethys Ocean being a kind of a proto-Mediterranean sea, which joined Atlantic and Indian oceans up until the early to mid-Tertiary.

This concept revived an old idea put by the French naturalist Henri Ducrotay de Blainville in the 19th century. Blainville indeed was the first in 1836 to classify together elephants and sirenians only, under the name "les gravigrades," i.e., beasts with a heavy gait, a name first used by him for elephants only. Blainville did not formalize this name scientifically, and Gravigrada was then used for a group of extinct ground sloths. Earlier, Linnaeus in his "Systema Naturae" of 1758 classified elephants and sirenians together under the name Bruta, but also with sloths and anteaters, with a very weak argument (the lack of front teeth). Blainville was impressed by the fact that manatees and elephants shared a distinct dental replacement, called "horizontal tooth displacement," a character that now is considered to be a CONVERGENCE. In elephants and manatees the tooth row is never complete: the anterior molars are lost before posterior ones erupt so that posterior molars take the place of anterior molars, moving anteriorly. In manatees this pattern is associated with polydonty, i.e., the existence of supernumerary molars. In elephants the number of molars is not altered but the three deciduous premolars and the three permanent molars erupt successively during life; in other words, the last molar (M3) is never associated to the first one. Among sirenians this character evolved only in manatees, and it appeared among proboscideans only in Neogene taxa.

I. Characters of Tethytheres

Various characters understood as synapomorphies support a sister group relation between Sirenia and Proboscidea. A few characters based on soft anatomy can only be seen in extant taxa: a bifid apex of the heart, with each ventricle being separated from the other at the tip (a convergence with some large cetaceans), a single pair of pectoral mammae (also seen on other mammalian taxa, but not in those more or less related to tethytheres). Others (osteological and dental characters) can be checked in fossils and define the Tethytheria at their ancestral node. They are a processus zygomaticus of the squamosal expanded laterally, an anterior orbit above the premolars with infraorbital canal under the orbit (Fig. 1), the reduction of the mastoid process, and bilophodont bunolophodont molars. This last character can be explained relatively easily. On the upper molars a posterior crest (loph) is made by three cusps, which are in line (metacone, and metaconule close to hypocone, a condition needed for development of a transverse loph called metaloph); on the lower molars the four main cusps are arranged in two crest-like rows, one anterior and one posterior.

II. Proboscideans

The order Proboscidea is represented by two extant species only, which are the biggest terrestrial mammals today: *Elephas maximus,* the Asian elephant, and *Loxodonta africana,* the African elephant. Approximately 160 fossil species are recognized since the late Paleocene. It is very likely that the earliest proboscideans were amphibious, an adaptation probably inherited from the hypothetical ancestral species of tethytheres.

Eocene proboscidean genera such as *Moeritherium* (discovered in Egypt, Mali, Libya, and Algeria) and *Numidotherium* (discovered in Algeria) were described as having amphibious characters. The low cranium of *Moeritherium* (Fig. 1A), with sirenian proportions, has a tubular shape with no postorbital constriction, high anterior orbits, and high auditory meatus, traits associated with amphibious habits, with the long body and short limbs (Fig. 2). The nasal fossa is not pushed backward, suggesting that no trunk was present. *Moeritherium* was of the size of a pig. *Numidotherium* was slightly taller (tapir sized) with a shorter body. The cranium was higher but still with anterior orbits and high auditory meatus (Fig. 1B). Postcranial bones display distinctive features unknown in

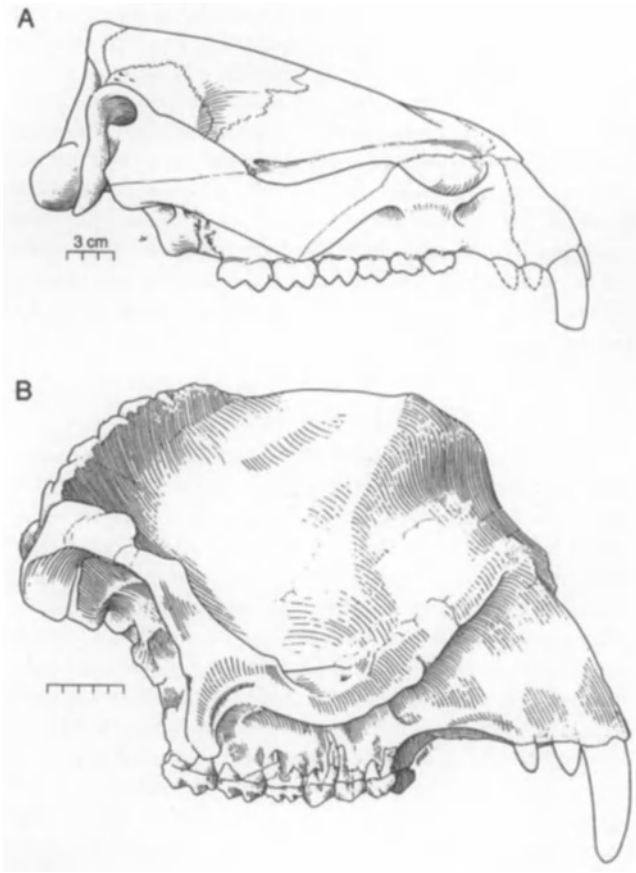

Figure 1 *Crania of Eocene proboscideans showing a tethythere feature despite different overall morphologies: the orbit is located above the anterior premolar. A more derived proboscidean feature is the opening of the orbit in the maxilla and not the jugal. (A)* Moeritherium lyonsi *from the Eocene of Libya. Scale: 3 cm. (B)* Numidotherium koholense *from the Eocene of Algeria. Scale: 5 cm. Drawings by Dominique Visset.*

Figure 2 *Reconstruction of the fossil proboscidean* Moeritherium, *late Eocene and early Oligocene of North Africa (Museum National d'Histoire Naturelle, Paris; photograph by P. Tassy). Proportions of skull, body, and legs are markedly different from those of elephants. Its gait was probably primitive, not the unusual gait of elephants, which lift two feet on one side at the same time. Copyright © Pascal Tassy.*

Moeritherium and in elephant-like proboscideans. The shoulder and hip joints are permanently abducted (or semisprawling), more reminiscent of the semisupinated position of aquatic mammals, such as sirenians, desmostylians, and pinnipeds. This contrasts markedly with the subunguligrade gait of modern proboscideans. Extant sirenians and elephants lack tubular perspiratory glands and this may be a character inherited from an amphibious (but not fully aquatic) common ancestor.

The earliest known proboscidean is *Phosphatherium escuilliei*, a small species (the size of a fox) described in 1996 from the phosphates of the Ouled Abdoun basin, Morocco, an area previously known to yield marine fauna, especially shark teeth. The only fossils known for the genus are two partial maxillae with premolars and molars. Its teeth are relatively generalized, making it difficult to identify these teeth to proboscideans if it were not for the knowledge of Eocene and Oligocene taxa found elsewhere in North Africa: *Moeritherium*, *Numidotherium*, and *Barytherium*. The teeth of *Phosphatherim* are very similar to those of *Numidotherium koholense* from Algeria, a truly lophodont proboscidean. Hence, during the late Paleocene and Eocene, proboscideans underwent a small radiation, of lophodont and bunolophodont taxa. The largest lophodont taxon is *Barytherium* from Egypt and Libya, which was similar in size to a living elephant. A lophodont lineage, the deinotheres, survived in the Neogene of Africa and Eurasia (up to 1.5 million years in Africa).

Anthracobunids are puzzling tethytheres from the Eocene of Pakistan and India, often closely compared to Proboscidea. Most of the known material consists in portions of maxillae, mandibles, and isolated teeth. Teeth are bunodont and more primitive than those of the bunolophodont contemporaneous African proboscideans. Postcranial remains allocated to anthracobunids (scapula, astragalus) match with those of proboscideans, especially the astragalus, which is the serial type and has a medial tuberculum (however, because no astragalus is known in primitive sirenians the proboscidean characters of the astragalus could well be tethythere characters).

Although early differentiation of elephantoids took place in Africa, elephantoids dispersed into Eurasia in the early Miocene, and probably even earlier, when the Arabo-African plate connected Eurasia closing the eastern Tethys. Elephantiformes such as *Phiomia* are bunolophodont, with an ever growing pair of upper and lower incisors (tusks), a long face with retracted nasal fossa (presence of a trunk), and a long mandibular symphysis. They do not show the horizontal tooth displacement only known in Miocene (and later) taxa. Elephantoids differentiated into several main groups with diverse shapes of crania and upper and lower tusks. Modern elephants are rooted in one of them, usually called "tetralophodont gomphotheres." with extra lophs on molars, shorter crania, and extended lower tusks, which are associated with a shorter mandibular symphysis. Stem elephants (*Stegotetrabelodon*) are known from the late Miocene of Africa and the Arabian Penin-

sula. The earliest elephants related to the extant genera *Loxodonta* and *Elephas* are contemporaneous in the fossil record, known as soon as the late Miocene (circa 6 millions years) in Uganda and Kenya.

III. Other Fossil Tethytheres

Extinct orders often classified as tethytheres together with Sirenia and Proboscidea are the Desmostylia and Embrithopoda. They share with Sirenia and Proboscidea the anterior orbit and the expanded zygomatic process. They share with the proboscideans the loss of mastoid process ("amastoidy"). However, hands (and feet) are not serial, contrary to both Sirenia and Proboscidea. The horizontal tooth displacement appeared also during the evolution of Miocene desmostylians.

Embrithopods are known in the late Eocene and Oligocene sediments of Egypt, Turkey, and Romania. Despite their very different overall morphology, they share a few derived characters with proboscideans: the loss of hypoglossal foramen (the hypoglossal nerve leaves the cranium by way of the foramen metoticum), the processus ascendens of the palatine bone is reduced greatly in the orbitotemporal fossa, and the astragalus has a prominent medial tuberculum, although the foot is not serial.

Extant tethytheres are also characterized by an unusual ontogenetic character. During the inner ear ontogeny of elephants and sirenians, the perilymphatic foramen fails to subdivide into two foramina so that the perilymphatic duct persists until the adult stage. This trait, probably paedomorphic, is not present in several Paleogene taxa such as the most primitive known sirenian (*Prorastomus* from the Eocene of Jamaica) and the Eocene proboscidean *Numidotherium* from Algeria. As a consequence, it is probably a convergence that appeared among sirenians and proboscideans. Moreover, this character is also known in embrithopods (the genus *Arsinoitherium* from Egypt), which probably is another convergence.

Thermoregulation

MICHAEL CASTELLINI
University of Alaska, Fairbanks

Marine mammals have had to develop methods to retain heat in cold seas (physiologically, biochemically, anatomically, or behaviorally), yet must be able to lose excess heat when they are on land or extremely active in the water. If the problem were one of simply evolving methods to stay warm in a cold ocean, it would be much easier to wrap themselves in deep blubber and fur or to stay very active and not have to deal with the consequences of heat loading. However, the difficulty of that solution is that the animal could get too warm, which would in turn would cause problems with metabolic regulation, reproductive chemistry, neural function, and so on. Thus, the thermoregulatory mechanisms that have evolved in marine mammals function not only to conserve heat, but to dump it when necessary. As poorly insulated humans, we must bring our artificial insulation with us and use exposure suits, wet suits, and a variety of man-made materials if we are to spend any significant time in the sea. For marine mammals, the insulation is already on board and probably serves multiple purposes beyond just thermoregulation.

I. The Physics of Heat and Temperature

The terms "heat" and "temperature" are often incorrectly exchanged for one another, yet they have very different physical aspects. "Heat" is the energy that reflects the molecular motion of atoms and molecules. As energy, heat can flow from an area where the energy is high (something that is "hot") to an area where the energy is low (something that is "cold"). We quantify how hot something is by using a variety of temperature scales (Kelvin, Celsius, Fahrenheit), Thus, the temperature of an object is our definition of the level of heat energy contained by that object. The unit of energy is the calorie, and a single calorie is defined as the amount of heat necessary to raise 1 g of water by 1°C. In common usage in the United States, the calorie associated with food and dieting is actually the kilocalorie (kcal; 1000 calories). In strict scientific terms, a single calorie is defined as 4.184 J.

As with any energy that flows, there is usually some sort of resistance that impedes the flow of that energy. In the field of thermoregulation, that resistance is insulation (the inverse of insulation is thermal conductance). Thus, poor conductors are excellent insulators. Blubber, for example, makes an excellent insulator and conducts heat poorly. The unit of conductance is represented by the term "k" and has the units of calorie sec^{-1} cm^{-1} $°C^{-1}$. These units define how many calories will flow through an insulator that is 1 cm thick per second for every degree Celsius difference between the hot and the cold side. Materials such as silver have an extremely high k value and thus conduct heat very well. Relatively, water is a better insulator than silver by 1000×. However, the point that is relevant to marine mammals is that air is a better insulator than water by

25×. In other words, water conducts heat away from a warm body 25× more effectively than air. This becomes an important point for the discussion of how fur works to help keep some marine mammals warm.

One final physics description is the definition of how heat flows from a warm to a cold object. Heat will flow when there is a temperature gradient between two sides of a conducting material depending on the magnitude of the temperature gradient, the thickness of the material, the inherent thermal conductance of the material, and the area that is exposed to the gradient. In biological terms, this means that heat would flow from the interior of a warm blooded mammal through the fat and skin to the cold outside air or water. Because water conducts heat 25× times more effectively than air, this means that heat flows out of a warm object in the cold water much more efficiently than it does when that same object is in air. Thus, as humans, we can easily stand around outside in 70°F air, but would find being in 70°F water very cold after a while. This principle states that the thicker the insulator, the less heat flow, and the larger the temperature gradient, the greater the driving force. Therefore, to stay warm, an animal would want an effective insulator, a small surface area (reduced appendage size, rolling up into a ball, etc.), a low temperature gradient (seek a warmer area or allow the body temperature to fall, i.e., hibernators), and have a thick insulator. An excellent general discussion of the physics of heat and energy transfer can be found in Schmidt-Nielsen (1997) and in Kooyman (1981) for marine mammals.

II. What Is "Thermoregulation?"

Having discussed the physics of heat, the next step is to define the act of regulating temperature (thermoregulation) in the biological realm. In the broadest sense, animals can be classified as either endotherms or ectotherms, although some animals cross between those two stages. An endotherm is an animal that generates and controls its internal heat so that its body core temperature can be regulated at a level different than ambient. Birds and mammals are the most commonly cited examples of endotherms. However, an ectotherm is an animal that allows its body temperature to mimic and follow the ambient temperature. Most fish and invertebrates are ectotherms. All marine mammals are endotherms and regulate their normal body temperature at about 37°C. Animals that hold their body temperature constant are called homeotherms while those that vary body temperature are called heterotherms. Most mammals are therefore homeothermic endotherms, although there are fascinating new data that suggest marine mammals may let their body temperature vary quite widely.

What is the importance of 37°C to a mammal? Perhaps the most critical point is that the actual value of 37°C is not as important as the constancy of that value. There are no biochemical or physical requirements about 37°C that make it the perfect temperature for a mammal, and most isolated biochemical reactions still work above and below that temperature. However, the mammalian body has evolved to balance its myriad of biochemical reactions at 37°C. If an animal gets much warmer or colder, the system comes out of equilibrium and there can be significant failures in metabolic regulation. Thus, the study of hibernators is a fascinating example of adaptation to this problem. There is a concept in thermal chemistry called Q_{10}, which is defined as the change in the rate of a reaction for every 10°C change in temperature. In most biological systems, Q_{10} is about two. This means that if the temperature of an animal increased by 10°C, its metabolic rate would probably double. Because the millions of chemical reactions in the body all have slightly different Q_{10} values, it is easy to see how small changes in the core temperature could disrupt the biochemical balance. Some reaction rates would increase more than others and the flow of molecules from one biochemical pathway to another would be compromised.

The goal of thermoregulation then is to maintain a constancy of temperature by adjusting all the properties discussed earlier (the temperature gradient, the conductance, the surface area, etc.). Of course, for an endotherm, there is the additional factor that the animal is generating heat through metabolic processes. To maintain a constant body temperature for an endotherm, the produced heat must equal the heat lost to the environment. Put on too much of an insulator and the core temperature goes up if metabolic heat production stays constant. The perfect example is a human in Alaska wearing a thick, down jacket outside in the winter to stay warm but getting much too hot on cross-country skis wearing that same down jacket. The analogy to marine mammals is straightforward: a whale or a seal may put on large amounts of blubber but, as a consequence, overheat when extremely active. A human can simply take off the down jacket while exercising. A whale, however, does not have the option of taking off its blubber layer; it must be able to dump heat and therefore thermoregulate using other methods.

There are several ways in which heat is transferred to the environment from a warm body. Evaporation is the process of dumping enough heat into a liquid to turn it into a gas. This is the process of cooling down by sweating. Radiation is the movement of heat through the release of electromagnetic energy from the warm body to the cold environment without physical contact (heat energy from the sun traveling through space and warming the earth or a whale radiating in the infrared wavelengths; Cuyler *et al.*, 1992). Conduction refers to the transfer of heat energy (calories) by physical contact between the warm body and the cold environment (putting your hand into cold water). Finally, convection is a specialized case of conduction where the heat that is transferred from the warm body is moved away from the area by a current of air or water. Thus, the environment provides an infinite sink for the heat (wind chill is the example in air or moving through very cold water as opposed to staying still in the water).

On the whole then, in order to maintain a constant body temperature, the heat that is generated in an endothermic mammal must be balanced by the heat lost or gained through radiation, evaporation, conduction, and convection. This is the fundamental equation of thermoregulatory biology.

There is a long and fascinating history to the study of thermoregulation in mammals. In the modern era, the study of arctic mammals and birds under cold conditions and the definition of the "thermoneutral zone (TNZ)" came about largely

from the work of Laurence Irving and Per Scholander (1950). The thermoneutral zone is the range of temperature over which an endotherm does not need to regulate its metabolism in order to maintain its body temperature constant. At the lower critical temperature, for example, a mammal would need to increase its heat production in order to stay warm. A great deal of this theory depends on the quality of fur for terrestrial mammals, and detailed studies on the thermal properties of fur were also addressed about the same time by Harold "Ted" Hammel (1955).

III. Thermoregulation in Marine Mammals

So far, all of this discussion could be applied to any biological system, not just marine mammals. Is there anything unique about thermoregulation in this group of marine endotherms? Both King (1983) and Riedman (1990) provide some excellent summaries of the broad field of thermoregulation in this group of mammals.

A unifying characteristic of most marine mammals is that they spend a great portion of their lives, if not their entire lives, in a liquid environment that is significantly colder than their core temperature of 37°C. Based on the discussion earlier on the fundamental aspects of thermoregulation, it should be clear that this aquatic life represents a significant thermal challenge to these mammals. While radiation and evaporation are probably insignificant sources of heat loss, conduction and convection are massive. However, in the Antarctic, seals will move to the relatively warm polar water (at −1.8 C°) when the real or wind chill temperature outside falls below about −40 C°. Clearly, there is a balance where the extreme cold of the ice-covered water, even with its higher thermal conductance, represents less of a thermal challenge than being outside on the surface.

Marine mammals use either fur or blubber for insulation and, like all endotherms, balance their metabolic heat production with various pathways of heat loss. However, the use of blubber or fur has its own biological costs. While blubber is used for thermoregulation, it is also a primary source of metabolic fuel for a marine mammal and plays a role in buoyancy regulation. Blubber is a fairly unique tissue for marine mammals and is not found outside of that group except for a similar tissue in POLAR BEARS (*Ursus maritimus*) and some penguins. Fur, however, is found in both terrestrial and marine mammals. However, the highest quality (density) fur is found in the sea otter. Fur is a very good insulator as long as it is carefully maintained, groomed, and kept dry on the layer next to the skin. Fur seals and sea OTTERS (*Enhydra lutris*) spend up to 12% of the daily energy use just maintaining their fur coats.

A. Heat Conservation and Generation

Marine mammals have no unusual heat-generating mechanisms or tissues that are not seen in any other mammal. For example, while some large warm-bodied fishes have specialized heat-generating tissues behind their eyes, no such organs or tissues exist in marine mammals. Some old data suggest that marine mammals may have an elevated metabolic rate for their mass, but this theory is not generally currently accepted (Lavigne and Kovacs, 1988) with the possible exception of the sea otter. The only heat-generating specialized tissue that has ever been found in marine mammals is brown fat in harp seal (*Pagophilus groenlandicus*) pups (Blix *et al.*, 1979). This tissue is thermogenically active via oxidation of lipid compounds, but only for about the first 3 days after birth. This is an important source of heat for these young pups, but not unique, as brown fat is found in other terrestrial mammals where it serves the same purpose. As noted earlier, marine mammals also have a typical mammalian body core temperature. In fact, upon close examination of the data, there appears to be nothing special about marine mammals that would distinguish them from terrestrial mammals when it comes to heat-generating mechanisms or abilities. Like the hibernators though, they may be able to tolerate more significant alterations in body temperature gradients than most terrestrial mammals.

Given the particularly nondescript aspects of marine mammal heat generation, there must be something that is different about them since they can live in an extremely cold liquid environment that would be fatal to all terrestrial mammals. Again, given the fundamental balance equation of thermoregulation, this suggests that they must have adapted significant ways to alter the heat loss through reduced conduction and convection. They have done this through the use of blubber, fur, and vascular adaptations.

B. Blubber

Blubber is most often incorrectly assumed to be an inert fat layer beneath the skin. However, it actually is a complex, active tissue that consists of a loose, spongy material where the matrix of the sponge is made up of collagen fibers and the volume is made of adipocytes (fat, or lipid cells). As the blubber layer increases or decreases, the collagen matrix remains the same, and it is the movement of lipid in and out of that matrix that accounts for the change in blubber quality and characteristics. However, all blubber is not the same; it varies from species to species in terms of the ratio of collagen to lipid and it can even vary within the same animal from location to location or with depth. Blubber depth can range from just a millimeter or two in newborn pinniped pups to 50 cm in large whales. The key issue here is that blubber, by itself, is a good insulator, as it can be up to 93% lipid with very little water content and has roughly the thermal conductance of asbestos. Because lipid has a conductance of only about one-third that of water, it acts as a relatively good insulator. Blubber acts as an internal insulator for marine mammals because it occurs below the skin layer. Therefore, the skin layer itself will be only marginally warmer than the surrounding water. In polar waters, for example, the skin of a whale or a seal would be just a degree or two above freezing. The thermal gradient exists from the skin surface to the tissues and organs in the core.

In addition to varying between species and with location, blubber can also vary across time in the same animal. This can be seen in the significant seasonal variation in blubber thickness in a seal as it moves between the breeding season (where it is fattest) and the leaner periods associated with molting and mating. For example, northern elephant seals (*Mirounga*

angustirostris) can range between 50% to less than 20% body fat depending on the season. Clearly, this temporal change in blubber impacts not only thermoregulation, but also buoyancy and energy reserves during periods of fasting or lactation. Consequently, the role of blubber and its relative thickness as an indicator of nutritional condition has been followed quite closely in recent studies that seek to address the population health of marine mammals. If a population of marine mammals is nutritionally compromised, one would hypothesize that the blubber layer should be reduced due to consumption of the blubber as a fuel source.

Blubber should be thought of as a very dynamic tissue with multiple stressors and pressures on its biology. Because it is a critical tissue for several different processes in marine mammals, it cannot be modeled in a strictly thermal scenario. For example, during a time of fasting, the animal will be utilizing blubber heavily, which would be inconsistent if it were also being challenged with an increasing thermal demand. Hence, fasting periods associated with breeding occur in warmer months or in warmer water for most marine mammals. Rosen and Renouf (1997) have written about the relationships between blubber seasonal distribution and thermal problems in seals.

C. Fur

As with terrestrial mammals, fur in marine mammals functions by trapping dry air next to the skin and keeping water (or cold air for a land mammal) away from the skin surface. Thus, the gradient here is from the skin outward with a warm skin surface and cold outer layers of the fur. The most-cited example of the use of fur by a marine mammal is that of the sea otter and it provides an excellent example of how this animal lives in a cold environment (Williams *et al.*, 1992). The sea otter is faced with a major thermal challenge, as it is a small mammal (large surface area to volume ratio through which to lose heat). It utilizes a dense fur with a series of guard hairs and underfurs to keep its skin warm. However, the cost of this luxurious fur coat is a tremendous amount of maintenance with up to 12% of daily energy expenditure being spent on grooming the coat. This is an absolutely essential cost, however, as without the fur, the animal would lose too much heat to the marine environment.

Many species of seals utilize blubber for thermal protection as adults, but will use a specialized fur, called lanugo, as newborns. Lanugo, or pup fur, is a very effective insulator in the air and is usually both long and very "fluffy." On newborn pups, it functions as protection against the cold air during the time that they are on land or ice for nursing. Lanugo is useless in water and allows the skin to chill to essentially water temperature. A pup must shed its lanugo and develop a significant blubber layer before it can enter the water and be an effective swimmer and diver. Not all species of seal or sea lion pups are born with lanugo, but its purpose is well documented in many cases. Lavigne and Kovacs (1988) provide an excellent description of the first few days of life for harp seals as they adapt from the warm temperature inside the womb to the icy cold of being born on the ice.

It is the reliance on a high-quality fur in the sea otter and fur seals that makes these mammals particularly vulnerable to oil spills. Oil permeates the fur and destroys the air pockets that provide the thermal insulation for the animal. After the *Exxon Valdez* oil spill (EVOS) in Alaska, there was a massive clean-up operation on the hundreds of sea otters that were brought to rescue and rehabilitation centers. The goal was to clean the fur to restore its thermal insulation properties. However, cleaning the fur of man-made oils also cleans the fur of the natural oils (primarily squalene) that help make the fur water resistant. Therefore, small amounts of lipid had to be added and groomed back into the fur of the otters after they were cleaned of the heavy oil. For a general summary of the impact of the EVOS event on marine mammals, see Loughlin (1997); for a detailed discussion on otters, see Williams and Davis (1995).

D. Vascular Adaptations

It is in the area of vascular adaptions for thermoregulation that marine mammals have evolved several unusual adaptations. The first of these is termed the *rete mirabile*, which is Latin for a "wonderful net." This net, which is a countercurrent heat exchanger (Scholander and Schevill, 1955), involves an intertwined network of veins and arteries such that the cold blood returning from the extremities in the veins runs next to the warm blood going out to extremities in the arteries. From the previous discussion on heat flow, it is easy to see how the heat flows from the arteries to the close-by veins thus tending to conserve the heat in the interior and cool the arterial blood going out to the colder regions of the body. Marine mammals have exquisite control of blood flow in their body not only for thermoregulation but also for diving. However, these two demands are themselves interrelated, and the control of one impacts the control of the other. For example, it would do no good for a diving seal to be closely controlling blood flow for oxygen conservation but then to override that control to dump or gain heat. In fact, Elsner and Gooden (1983) discussed some experiments with seals where the diving response inhibited thermoregulatory-driven circulatory adjustments. In another innovative study, divers were able to apply heat flow probes to the skin of dolphins while both divers and dolphins were underwater. The results show that the animals tend to defer heat regulation and favor oxygen conservation vascular adjustments when both must coincide (Noren *et al.*, 1999).

These retes are found in several locations in marine mammals (and in some cold-adapted birds), with the most-cited examples being in the flukes of whales and the flippers of pinnipeds (Tarasoff and Fisher. 1970; Kvadsheim and Folkow, 1997). There has been the fascinating description of another rete, but in this case, the rete is used to cool down the reproductive organs of dolphins and seals by bringing in cold blood from the extremities (Rommel *et al.*, 1995).

The next vascular adjustment seen in marine mammals deals with those mammals that utilize thick blubber as an insulating material. As mentioned several times earlier, this is a good technique for staying warm, but can cause serious problems if trying to cool. In fact, large whales have such a tremendous thermal mass and a low surface area to volume ratio that they may have a much more serious problem dumping heat than conserving it (Hokkanen, 1990). Because marine mammals do

not sweat, the answer is that blubber is not just an inert organic blanket surrounding the animal, but is instead vascularized with a series of anastomoses, or blood flow shunts. These shunts can control the amount of blood moving through the blubber and reaching the skin, thereby controlling the amount of heat lost to the environment. If a seal needs to dump heat, the anastomoses open and warm blood can reach the surface of the skin. When Weddell seals (*Leptonychotes weddellii*) in the Antarctic dump excess heat, clouds of steam come off the animal as the blood reaches the surface of their skin. In some cases, the seals get so warm that they partially melt their way into the ice and leave perfect "seal shadows." Conversely, when these shunts are closed, the same seals will be completely covered in snow with no signs of melting at any location except near the eyes and nose.

As mentioned earlier, the balance of blood flow throughout the body of marine mammals can be complex and is controlled by multiple demands: diving, exercise, and heat regulation. Diving requires limited blood circulation, simultaneous underwater exercise requires increased circulation, and thermoregulation can require both. How these animals balance those conflicting demands is an area where much more work needs to be done. This can be seen in even simple manipulations of seals and sea lions. When taking blood samples from the flippers of pinnipeds, the flippers must be warm or there is no blood flow out to the periphery. However, if anesthesia or sedation is required to work with the animal, those procedures may also cause a series of vascular adjustments and can dump great amounts of heat quickly. Then, extra heat needs to be added to the animal to keep the core temperature up and blood flow open to the flippers.

The balance between diving and thermoregulation has another interesting aspect if one looks at it from the point of view of DIVING PHYSIOLOGY. One of the central demands for diving is that oxygen must be conserved in order to extend the dive. This can be done by a variety of means and one of those means is to reduce the demand for oxygen by reducing the metabolic rate. In the discussion earlier, the concept of Q_{10} was mentioned, which describes how a reaction rate changes with temperature. If a marine mammal were to reduce its body temperature while diving, the impact from the Q_{10} relationship would therefore decrease the demand for oxygen, thus extending dive time. There is some evidence from freely diving pinnipeds suggesting that the animals can drop their core temperatures during diving and would thus gain some diving time by reducing the metabolic rate. The exact mechanisms by which this is done are not yet known, but temperature drops have been described in freely diving Weddell seals (Kooyman *et al.*, 1980; Hill *et al.*, 1987) and northern elephant seals (Andrews, 1999).

E. Behavioral Thermoregulation

Most of the mechanisms discussed earlier are biochemical, anatomical, or physiological mechanisms for regulating heat production or loss in a marine mammal. Of course, a marine mammal is not a static system and the animal can alter the demands placed upon it with behavioral modification. For example, sea otters are often seen floating with all four paws out of the water. The paws are highly vascularized, but not well insulated with fur. Thus, they would be a tremendous source of heat loss if in contact with the water. The otters keep their paws away from the water if they are trying to stay warm. Similarly, it is not unusual to see rafts of California sea lions (*Zalophus californianus*) floating at the surface with their large foreflippers extended out of the water. On the beach, both seals and sea lions will move up or down the tidal zone area to either cool off or warm up. When too hot, sea lions will maximize their surface area by spreading out their flippers, while if too cold, they will lie on top of their flippers. As discussed earlier, Weddell seals will head to the water if the actual or convective temperature drops below about −40°C. However, elephant seals will flip cool sand onto their backs to help keep their body temperature down on sunny days, and Hawaiian monk seals (*Monachus schauinslandi*) will find shade under bushes or in small ravines out on hot, sandy atolls. All of these behavioral mechanisms are not unique to marine mammals, however, except that the animals have the ability to use the sea to cool down as necessary. A good example of both feeding and thermoregulation are the humpback whales (*Megaptera novaeangliae*) that come into cool Alaskan waters during the summer for feeding, but head south to warm, Hawaiian waters for breeding. A review of these behavior patterns for pinnipeds is found in King (1983).

IV. Summary

What are the essential elements of thermoregulation in marine mammals? Like all endotherms, these mammals must obey the physics of heat balance when holding body temperature constant. The methods for producing heat (resting metabolism and exercise) must balance the windows for heat loss (primarily conduction and convection) (Whittow, 1987). Because marine mammals do not appear to have any special adaptations for producing excess heat, most of their ability to thermoregulate comes with their ability to control heat loss. Control of these heat loss mechanisms is via biochemical, anatomical, physiological, and behavioral means. However, as in all levels of adaptation to the environment, systems cannot be considered or modeled in isolation. The problem with balancing blood flow for thermoregulation while also controlling blood flow for diving is an excellent example of this problem.

It is easiest to observe the behavioral means that marine mammals use to stay warm or to cool down: the movement up or down a beach with the tide, the use of shade, flipping of sand, swimming to warmer or colder water, exposing flippers, etc. Behind all of these behavioral patterns are the physiological or anatomical mechanisms that make the behavioral patterns effective. Countercurrent heat exchangers, blood shunts under the blubber, and even the chemistry of the blubber and the microstructure of the fur are all part of the thermoregulatory system. Ultimately, however, we are still left with the paradox of heat balance in marine mammals: they live in a cold, thermally challenging environment that no terrestrial mammal could survive. However, the very means they have utilized to stay warm in cold seas have come at a cost: for many species, they have had to also evolve the means to get rid of excess heat.

The exquisite balance between all these competing demands and systems is what makes the study of thermoregulatory biology in these mammals such a rewarding experience.

Tool Use

RACHEL SMOLKER
University of Vermont, Burlington

Modern humans make use of a plethora of tools, ranging from the simple hammer and screwdriver to the sublimely complex space probe, guided missile launch, or magnetic resonance imagery device. Even our ancient ancestors crafted fine arrowheads and spears out of stone, bone, and wood. Until quite recently, we considered tool use to be a hallmark of our species, yet another indication of our superior intelligence and manipulative skill. Then in the mid-1960s, Jane Goodall made the startling discovery that chimpanzees used tools—twigs that were carefully selected and modified appropriately—to fish for termites.

Since then, the study of animal behavior has grown tremendously, and more and more wildly diverse creatures have been discovered to use tools in one way or another: Finches probe for grubs under bark using thorns, sea otters (*Enhydra lutris*) pound open abalone shells using rocks, caddisfly larvae encase themselves in suits of armor made up of bits of debris, and spiders weave webs. The need for a more rigorous definition of tool use became necessary, and Benjamin Beck (1980) devised one that is now widely accepted: "The external employment of an unattached environmental object to alter more efficiently the form, position or condition of another object, another organism or the user itself, when the user holds or carries the tool just prior to use and is responsible for the proper and effective orientation of the tool."

I. Sponge Carrying

By this definition, the sponge carrying of Indian Ocean bottlenose dolphins (*Tursiops aduncus*) in Shark Bay, West Australia, is a form of tool use (Smolker *et al.*, 1997). Sponge carrying was first observed in 1984. A dolphin, who was later

dubbed "Halfluke" because she lacked half of her tail, surfaced near the author's boat with a large, reddish, knobby "growth" on her face. She took several breaths at the surface and then dove, bringing her damaged tail flukes out of the water as she headed toward the bottom. After watching for some time it became evident that Halfluke was carrying something that she occasionally dropped. It was not a "growth," but rather a sponge. Halfluke was one of several dolphins who regularly carried sponges, usually within a particular deep-water channel within Shark Bay. These "sponge carriers" are all female (most have had offspring, and some of the offspring have subsequently taken up sponge carrying). The sponge carriers have been observed on numerous occasions during every year since 1984, almost invariably carrying sponges. They "specialize" in sponge carrying and have been doing so for years. On a few occasions, the author saw other dolphins carry sponges (see Fig. 1), but these were all single observations—usually just a single surfacing with a sponge—by dolphins that otherwise did not carry sponges.

From the surface, sponge carrying looks no different than other forms of foraging. The dolphin surfaces to BREATHE, traveling slowly along while taking several breaths and then dives, bringing her tail flukes out, an indication that she is diving down toward the bottom. After 2 or 3 min, she resurfaces further along. There is often no predictable travel direction: the dolphin appears to wander around while below the surface. Occasionally the dolphin surfaces without the sponge or trades in one sponge for another. The sponges (*Echinodictyum mesenterinium*) are roughly cone shaped and fit over the dolphin's beak. Some are quite large and flop back over the dolphin's face, even obstructing vision. Others are small and fit like a yarmulke cap, just covering the beak tip. The shape of the sponge and the backward pressure caused as the dolphin swims forward apparently keep it in place. Sometimes they do fall off and are quickly retrieved by the dolphin.

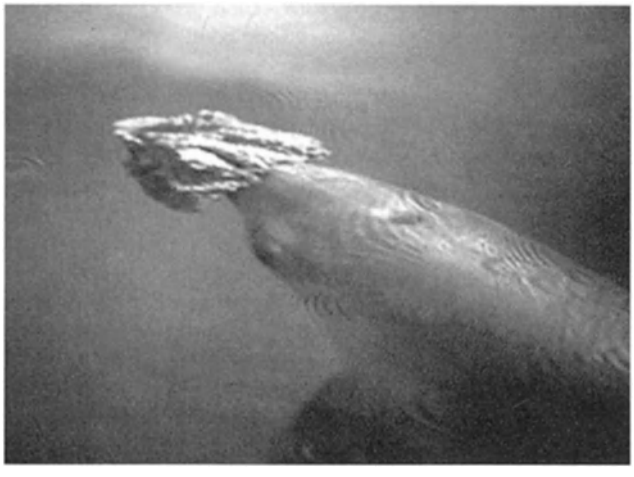

Figure 1 *Sponge carrying was observed first in dolphins of Shark Bay, Western Australia. The practice has been passed from females to female offspring and has an uncertain function.*

After years of observing sponge carrying, we have never seen for sure how the sponges are used, as the dolphins apparently make use of the sponges at or close to the bottom in deep and murky water. Given the amount of time that sponge carriers spend with sponges—similar to the time spent foraging by other dolphins—we suspect that the sponges are used in some way to aid foraging. Also, we sometimes saw sponge carriers surface rapidly without a sponge just prior to surfacing and swallowing some prey item. Thus the sponge is apparently used during search and then dropped during the final pursuit and capture of prey.

All evidence best fits with the hypothesis that the sponges are used as shields, protecting the dolphins' face and beak. They may be protecting themselves from the stingers or spines of noxious organisms encountered while foraging among rocky ledges or from abrasive sand, broken shell, and rocks while poking their beaks into the bottom in search of burrowing fish. We know that there are spiny lionfish in the area as well as stonefish and various other poisonous organisms. It is also known that the dolphins sometimes poke into the sandy bottom in search of prey.

The use of sponges as shields is not the first example of tool use by dolphins: Tayler and Saayman (1973) reported that a captive bottlenose dolphin used pieces of the tile to rub the tank walls, dislodging pieces of seaweed. Brown and Norris (1956) reported observing two captive common bottlenose dolphins (*T. truncatus*) attempting to capture a moray eel. After many attempts, one dolphin sought out and killed a scorpionfish, carried the fish to the crevice where the eel was hiding, and poked at the eel with the spiny fish. The eel abandoned its hiding place and was captured. These examples are indicative of the resourcefulness and intelligence of dolphins, but they are one-time behaviors. Sponge carrying is engaged in by several dolphins and has been ongoing for many years. It has not spread throughout the population as, for example, washing of sweet potatoes among Japanese macaques, but rather is restricted to a few individuals. Thus, like termite fishing by chimpanzees, sponge carrying is a well-established tradition of tool use by an animal living in a vastly different ecosystem and bearing little relatedness to humans.

Dolphins and sea otters appear to be the only marine mammals that engage in tool use.

Toothed Whales, Overview

SASCHA K. HOOKER
University of St. Andrews, Scotland, United Kingdom

Toothed whales comprise the suborder Odontoceti of the order Cetacea. This suborder includes 10 diverse families, 2 of which contain large numbers of species. There are at least 71 species in all, including the true dolphins, monodontids, river dolphins, porpoises, beaked whales, and sperm whales (Table I). These species occur in three primary clades, the superfamilies Delphinoidea (true dolphins, monodontids, and porpoises), Ziphoidea (beaked whales), and Physeteroidea (sperm whales), while the affinities of the river dolphins remain uncertain. With the exception of the sperm whale (males of which reach up to 18 m) and the larger beaked whale species (*Berardius* and *Hyperoodon* spp.), most odontocetes are small to medium-sized cetaceans, ranging in size from the Hector's dolphin (*Cephalorhynchus hectori*) (1.5 m) to the killer whale (*Orcinus orca*) (8.5 m). These species show a range of distributions, with some, such as river dolphins, found only in quite specific areas, whereas others, such as sperm whales or killer whales, show a global distribution.

I. Diagnostic Characters and Taxonomy

Odontocetes and mysticetes differ fundamentally in three major ways: the way that the bones of the SKULL have become telescoped, the specialized ECHOLOCATION system (and associated anatomy) of odontocetes, and the specialized FILTER-FEEDING mechanism of the baleen whales (Table II). The name Odontoceti derives from the Greek *odous* or *odontos* for "tooth" and *ketos* for "sea monster," hence "toothed sea monster," referring to the presence of teeth (Rice, 1998). In contrast, mysticetes do not possess teeth, but instead have baleen plates, which hang from the upper jaw and are used to filter small prey items from the water. However, although all odontocetes possess teeth, in some species (or sexes) these teeth are much reduced and may not erupt.

Other distinctive features include the possession of a single external naris or blowhole, whereas mysticetes have two blowholes. Most odontocetes show some degree of dorsal asymmetry in their skull and facial soft tissue, whereas all mysticetes have a symmetrical skull and facial soft tissue. Odontocetes possess a large ovoid melon in the anterior part of the facial region. This fatty tissue is thought to be an important component of the echolocation system. Although mysticetes possess a fatty structure just anterior to the nasal passages, which may represent a vestigial melon, this is only a fraction of the size of that present in odontocetes.

Odontocetes (with the notable exception of the sperm whale, *Physeter macrocephalus*) tend to be smaller in size than mysticetes, although there is some overlap. Odontocetes also show variation in SEXUAL DIMORPHISM. In some species, males are much larger than females (e.g., sperm whale, killer whale), whereas in others there may be reverse sexual dimorphism, in which females are larger than males [e.g., harbor porpoises (*Phocoena phocoena*), Baird's beaked whale (*Berardius bairdii*)]. Among mysticetes, adult females are always slightly larger than adult males.

The skull and jawbone of odontocetes also contain a number of diagnostic characteristics. The odontocete mandible is symphyseal (the two jawbones lock together in a bony symphysis anteriorly) and each jawbone spreads into a fat-filled hollow pan at the posterior, non tooth-bearing section, whereas mysticete mandibles are nonsymphyseal and are solid. When viewed from above, the odontocete jawbone is relatively straight, whereas the mysticete jawbone curves laterally. The maxilla of both odontocetes and mysticetes has "telescoped," migrating posteriorly to form the long rostrum and dorsal nasal openings. In odontocetes, the maxillae have extended outward over the orbits to form an expanded bony supraorbital process of the frontal bone. This process forms an anchoring point for the facial musculature associated with sound production (see later). In contrast, the maxillae of mysticetes project under the eye orbit and have developed bony protuberances anterior to the eye orbit. Odontocetes lack this antorbital process of the maxilla. The ear bone of odontocetes is also quite different from that of mysticetes. In odontocetes, the tympanic bulla and periotic bone are fused together, are of equal size, and are not fused to the skull. The odontocete tympanic is thin walled and conical, tapering anteriorly. In mysticetes, the tympanic bulla is much larger (nearly twice the volume of the periotic bone) and is thick walled and spherical. Bony flanges of the periotic wedge it against the skull such that only the large bulla can be removed.

The clear morphological differences between odontocetes and mysticetes suggest monophyly of the odontocetes. There has been some disagreement about this issue based on some molecular sequence data that supported a closer relationship between sperm whales and BALEEN WHALES than between sperm whales and other toothed whales. However, reanalysis of these data and more recent work on both morphologic and

TABLE I
Odontocete Families

Family	*Common name*	*No. species*
Kogiidae	Pygmy and dwarf sperm whales	2
Physeteridae	Sperm whale	1
Ziphiidae	Beaked whales	20
Delphinidae	True dolphins	36
Monodontidae	Narwhal and beluga	2
Phocoenidae	Porpoises	6
Iniidae	Boto (Amazon river dolphin)	1
Pontoporiidae	Fransiscana	1
Lipotidae	Baiji (Chinese river dolphin)	1
Platanistidae	South Asian river dolphin	1
	Total	71

TABLE II
Major Differences between Odontocete and Mysticete Suborders of Cetaceans

Odontocetes	*Mysticetes*
Teeth	Baleen plates
Single blowhole	Two blowholes
Dorsally asymmetric skull and facial tissue	Symmetrical skill and facial tissue
Presence of a melon	No melon
Variable size	Always large
Variation in sexual dimorphism	Always reverse sexually dimorphic
Symphyseal mandible	Nonsymphyseal mandible
Hollow pan bone of lower jaw	Lower jawbones solid, no pan bone
Maxillae project outward over expanded suprabital processess	Maxillae project under the eye orbit and possess bony protuberances anterior to the eye orbits
Tympanic and periotic fused and equal sized	Tympanic bulla much larger than periotic from which it separates

molecular data continue to support odontocete monophyly. Relationships among extant odontocetes are somewhat controversial, but there is a general consensus as to the order of branching of the phylogenetic tree, despite controversies over smaller scale relationships (Fig. 1).

Odontocetes first appeared in the fossil record in the late Oligocene, approximately 25 million years ago (Rice, 1998). Odontocete diversity increased during the warm temperatures of the early Miocene, during which time the earliest ziphiids and platanistids appeared in the eastern North Pacific. Middle Miocene diversity was also high and included diversification of these families, together with extensive radiation of the delphinoids, while the platanistoids progressively declined. Modern odontocete families are known from the late Miocene of the eastern North Pacific (monodontids and phocoenids) and western South Atlantic (pontoporiids) (Fig. 2). Evolutionary trends among odontocetes included the expansion and increase in size of the face, shortening of the intertemporal region, elevation of the cranial vertex posterior to the nasals, increased facial asymmetry, and isolation of the ear bones from the skull resulting in the diagnostic features described previously. There has also been a trend toward either long, slender jaws with an increased number of teeth or short, robust jaws and a reduced number of teeth.

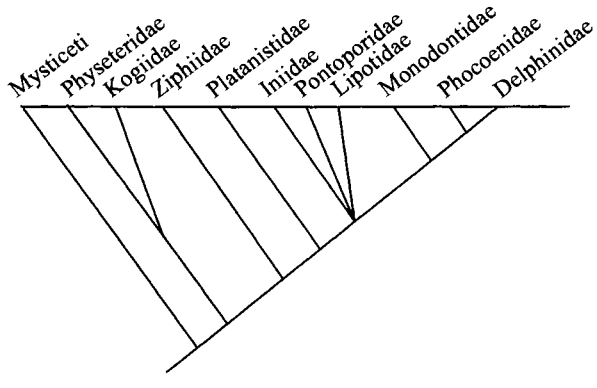

Figure 1 *Generally accepted odontocete phylogeny.*

II. Distribution and Range

Different odontocete species can be found across a wide range of habitats in all oceans of the world. The cyclical changes in sea level over the Quaternary (Pleistocene to Recent) period are thought to be responsible for much of the recent speciation within odontocete families. Sea level drops associated with cooling are suggested to have isolated populations, which then speciated allopatrically. The distributions of modern odontocetes

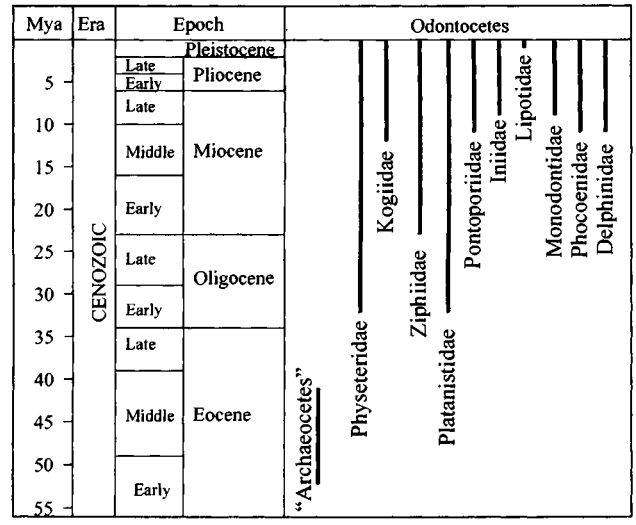

Figure 2 *Chronologic ranges of extant odontocete families. Mya, million years ago. (After Berta and Sumich, 1999; Rice, 1998).*

range from species found globally, such as sperm whales and killer whales, to those with more restricted coastal distributions, such as harbor porpoises. Some species are found only in polar regions, including the narwhal (*Monodon monoceros*) and beluga (*Delphinapterus leucas*) and others only in tropical waters, such as Fraser's dolphin (*Lagenodelphis hosei*) (Jefferson *et al.*, 1993). Segregation by warm tropical waters created antitropical distributions of some species pairs now found only in the Northern and Southern Hemispheres, respectively [e.g., the northern and southern right whale dolphins (*Lissodelphis* spp.), northern and southern bottlenose whales (*Hyperoodon* spp.)].

Few odontocetes show the kind of long-distance seasonal MIGRATION that is found among mysticetes. The only odontocete species known to show a large (ocean basin) scale of movement is the sperm whale. At approximately 10 years of age, male sperm whales leave their natal group in the tropics and subtropics and migrate to cold temperate and subpolar waters where they feed. Once physically mature they return to the tropics to breed. Other odontocetes may show much smaller migrations as they follow their prey movements [e.g., long-finned pilot whales (*Globicephala melas*) in the North Atlantic move from the shelf edge up onto shallower banks in response to changes in squid distribution]. Other species (e.g., killer whales) show negligible seasonal changes in distribution.

Many odontocete species show GEOGRAPHIC VARIATION across their ranges, leading to the definition of several subspecies or races. With increasing scrutiny of both genetic and morphological differences, subspecies and population level differences are continually being identified. In some cases, this is leading to revision of the currently established species (see Rice, 1998).

III. External Appearance

In general, many odontocete species tend to have darker COLORATION on the dorsal surface (back and cape) and lighter pigmentation on the ventral surface (Fig. 3). Such countershading is relatively common in the marine environment and functions essentially as camouflage, such that when viewed from above the dark dorsal surface is seen against the darker depths, and when viewed from below the lighter ventral surface is seen against the brighter downwelling light from the surface (e.g., harbor porpoise). Exceptions to this include the beluga, which has a uniform color pattern, although this is thought to be related to the bright ice-covered habitat that it lives in. The general tendency toward countershading has become quite elaborate in some species, which also have striped and saddle patterns [e.g., striped dolphins (*Stenella coeruleoalba*), short-beaked common dolphins (*Delphinus delphis*)], and has become radically modified in others [e.g., killer whale, Dall's porpoise (*Phocoenoides dalli*)]. It has also been suggested that these color patterns may function in signaling between individuals in a group (Norris *et al.*, 1994), in addition to their function in concealment (from both PREDATORS AND PREY).

Figure 3 *Common dolphin* (Delphinus *sp.) pigmentation shows countershading with dark pigmentation on the dorsal surface and light pigmentation on the ventral surface, common to most odontocetes. Photograph by Sascha K. Hooker.*

Odontocetes tend to show greater body flexibility than mysticetes. This is presumably due to differences in prey capture strategies between odontocetes, which chase fast, mobile, single prey, and mysticetes, which engulf less mobile prey schools. This flexibility is quite pronounced in some odontocete species (e.g., belugas).

IV. Diet and Feeding Strategies

Different odontocete species feed on fish, squid, large crustaceans, birds, and occasionally other marine mammals. They differ from mysticetes in that they generally chase, capture, and swallow single relatively large prey items rather than filtering and swallowing large quantities of small prey items. This more generalized and more adaptable feeding method is thought to account for much of the diversity of odontocete species and their range of habitats. Many odontocetes also feed on much deeper prey than the near-surface plankton diet of many species of mysticetes. Additionally, whereas the diet of baleen whales is highly seasonal due to the seasonal nature of zooplankton biomass and production, that of odontocetes is generally more constant year-round.

Unlike the heterodont condition of most terrestrial mammals, the teeth of odontocetes are uniformly shaped (homodont). There is wide variation between (and some variation within) species in tooth number, size, and shape. The teeth of most odontocete species tend to be cone-shaped with single, open roots. Exceptions to this include the porpoises, which have spade-shaped teeth, and the beaked whales, which show great variation in size, shape, and location of teeth in the jaw.

Narwhals have only two teeth, both in the upper jaw. In females, these teeth usually remain embedded in the upper jawbones, but in males the left tooth grows out through the front of the head into a tusk up to 3 m long. These tusks are thought to be involved in male–male competition. These are used primarily as a display, although males have been seen sparring with their tusks above the water. The teeth of beaked whales have similarly become adapted for use in male–male competition and generally erupt only in males. In some species, such as the dense-beaked whale (*Mesoplodon densirostris*), these teeth form large structures, which protrude above the upper jaw. In the strap-toothed whale (*Mesoplodon layardii*), the

teeth, which emerge from the middle of the lower jaw, curl backward and inward, extending over the upper jaw, often preventing it from opening more than a few centimeters.

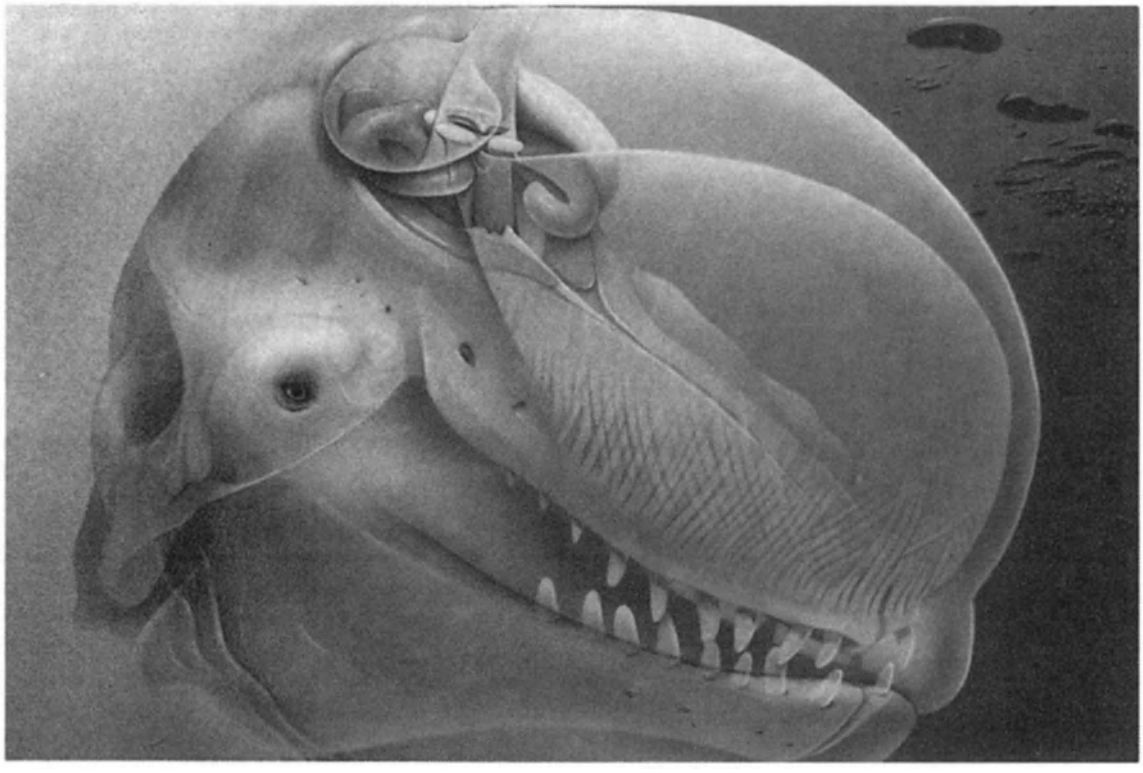
The DIET of a particular species is generally reflected in the morphology of the jaw and in the type and number of teeth. For example, species that feed primarily on fish tend to have more teeth (e.g., spotted dolphins, *Stenella* spp.) and use these teeth for grasping single prey. Species that feed primarily on squid tend to show reduced dentition [e.g., sperm whales, beaked whales, narwhals, Risso's dolphin (*Grampus griseus*)] and are thought to feed by suction. This suction is achieved by using the tongue as a piston in combination with a small gape. The suction-feeding mechanism of beaked whales was investigated in detail by Heyning and Mead (1996) and involves distension of the floor of the mouth by expanding the throat grooves together with retraction of the tongue by the styloglossus and hyoglossus muscles. Additionally, it has been suggested that some species may debilitate prey by directing high-intensity sounds at them prior to capturing them (Norris and Mohl, 1983). Such feeding methods are thought to explain the occasional observation of healthy animals with severe deformity of the jaws (as has been noted in sperm whales).

Notable specializations associated with odontocete feeding are shown by several bottlenose dolphin populations. In Shark Bay, Australia, a small number of Indian Ocean bottlenose dolphin (*Tursiops aduncus*) females have been observed carrying sponges (Mann *et al.*, 2000). These are thought to function as "tools" to protect the dolphin's rostrum as it roots in bottom coraline sediments in order to flush bottom-dwelling fish out. Another bottlenose dolphin (*T. truncatus*) population in North Carolina has been observed beaching themselves and the fish they were pursuing up onto the surrounding mud banks, thus immobilizing their fish prey, which they can catch easily, and then sliding or wriggling back down into the water (Reynolds and Rommel, 1999). The same behavior has also been observed in killer whales in Patagonia and the Crozet Archipelago in their pursuit of seals up onto steeply shelving beaches.

Foraging specializations of killer whales in British Columbia, Canada, and State of Washington waters have resulted in two separate forms: "transients," which feed on marine mammals, and "residents," which feed on fish. These two forms are thought to potentially represent a case of incipient speciation. The primary difference between these two forms is in their dietary specialization, which has resulted in their social separation and behavioral, morphological, and genetic differences.

Many odontocetes appear to feed throughout the day and night [e.g., sperm whales, northern bottlenose whales (*Hyperoodon ampullatus*)], but many smaller delphinids show marked diurnal differences in feeding [e.g., spinner dolphin (*Stenella longirostris*), pantropical spotted dolphin (*S. attenuata*)]. Because many prey species rise to shallower depths during the darkness of night, it is energetically more efficient for some species to conduct the majority of foraging behavior at night.

As mentioned previously, odontocetes tend to feed at greater depths than mysticetes. In general, however, detailed data on diving and foraging patterns of most species of odontocetes are not yet available. The use of novel technologies, such as the attachment of time-depth recorders to monitor dive profiles of these species, has lagged behind work done on pinnipeds or mysticetes, primarily due to difficulties in deployment, attachment, and recovery (Hooker and Baird, 2001). However, new developments in these technologies and attachment mechanisms are increasingly resulting in the initiation of new studies.



V. Sound Production and Reception

Toothed whales have developed specialized sound production and reception mechanisms for the use of biosonar. All modern odontocetes are thought to use echolocation in the same manner as bats to "image" their environment. Although only a few species of odontocete are unequivocally known to echolocate, all odontocetes known to produce pulse-like sounds in the wild are assumed to be able to echolocate.

The sound production mechanism of odontocetes consists of a sound generator located in the "monkey lips"/dorsal bursae (MLDB complex) associated with the upper nasal passages. In most odontocetes, there are two bilaterally placed MLDB complexes, but sperm whales have only a single complex. The central components of the MLDB complex are fatty dorsal bursae, monkey lips, bursal cartilages, and the blowhole ligament (Cranford *et al.*, 1996). Sounds are generated as air is forced between the monkey lips, setting the MLDB complex into vibration (Fig. 4). Sound is propagated into the water by the melon, a low-density, lipid-filled structure that acts as an acoustic lens to focus a directional sound beam ahead of the animal (see Au, 1993). The short-duration clicks produced as a result of this are used primarily for echolocation, although some species appear to use these clicks in a social context (e.g., Hector's dolphin, *Cephalorhynchus hectori*).

Most odontocete species produce broadband echolocation clicks in the ultrasonic sound range, well above the range of human hearing. The pulse duration, frequency, interclick interval, and source level are adjusted by the animal for optimal performance according to the prevailing conditions of ambient noise, reverberation, target distance, and target characteristics (Au, 1993). With low ambient noise, bottlenose dolphins, belugas, and false killer whales (*Pseudorca crassidens*) often echolocate using frequencies from 20 to 60 kHz, although at higher noise levels they emit stronger pulses at 100–130 kHz. Echolocation clicks of porpoises and many small dolphins are >100 kHz, whereas those of the sperm whale range from <100 Hz to 30 kHz, with most energy from 2 to 4 kHz and 10 to 16 kHz (Richardson *et al.*, 1995).

In addition to echolocation clicks and loud impulse sounds, many toothed whales also produce other sounds, usually described as whistles, squeals, or less distinct pulsed sounds such as cries, grunts, or barks (Richardson *et al.*, 1995). These tend to be narrow band (sometimes pure tone), frequency-modulated sounds, often with a harmonic structure. Most whistles tend to have most of their energy below 20 kHz. These whistles can show a variety of patterns of frequency and amplitude over the duration of the whistle. For any species, the frequency, duration, and level may vary. Observations of captive bottlenose dolphins have shown that individual animals can be identified from the contour of the whistle on a sonogram (a representation of the whistle as sound frequency plotted against

time). The distinctive character of a whistle is thought to function in identifying the sound producer to other animals. These whistles are therefore known as signature whistles. Evidence also suggests that there may be population or group level distinctions between whistles of bottlenose dolphins.

Group-specific sounds have also been found among KILLER WHALES and sperm whales. Among killer whales, groups appear to have a repertoire of approximately 10 calls. Different groups may share some but not all of the calls within their repertoire, and relationships between groups can be established based on the sim-

ilarities in their repertoires. In a similar fashion, the codas (rhythmic patterns of clicks) produced by sperm whales also appear to be characteristic of the social group (Mann *et al.*, 2000).

The high-frequency HEARING of odontocetes is reflected in the structures of the jaw and ear. The lower jaw of odontocetes is flared out in a thin hollow pan bone at the rear. This is filled with a fat body that connects directly with the bulla of the middle ear. These fat bodies act as low-density sound channels to conduct sounds to the ears. Within the ear, the tympanic bulla is separated from adjacent bones of the skull by peritympanic sinuses filled with an insulating emulsion of mucus, oil, and air. The bulla is suspended in this emulsion by connective tissue so that the middle ear functions as a sound receiver isolated from the skull to better localize sound signals. The tympanic bulla membrane of odontocetes is also stiffened with bony ligaments, which appear to be associated with ultrasonic hearing (Reynolds and Rommel, 1999).

VI. Social Organization and Culture

Toothed whales are particularly well known for their BRAIN SIZE and rich social lives (Mann *et al.*, 2000). The absolute brain size of odontocetes ranges from 840 g in common dolphins to 7820 g in sperm whales (Berta and Sumich, 1999). However, a more useful way to compare brain sizes is to use the ratio of brain size to body size, the encephalization quotient (EQ). The relative brain sizes of odontocetes (ranging from EQ 0.02% for the sperm whale to EQ 1% for the bottlenose dolphin) are much larger than for most terrestrial mammals, but are similar to those of anthropoid primates (EQ 0.3% gorilla). Captive studies of bottlenose dolphins have shown that dolphins may have a "pecking order" similar to that of chimpanzees, in which both males and females have a social hierarchy, but that generally males are dominant to females.

The social systems of only a few odontocete species are known from long-term studies of wild animals, but these suggest some novel adaptations to standard mammalian patterns (Table III; Connor *et al.*, 1998). In Shark Bay, Western Australia, male Indian Ocean bottlenose dolphins form tight associations with one or two other males with whom they cooperate to form aggressively maintained consortships with individual females. These alliances, or coalitions, further appear to form moderately strong associations with one or two other alliances and will defend each other in competition over females. A completely different strategy is found among the fish-eating "resident" killer whales living along the coast of British Columbia, Canada, and the State of Washington. Here, neither males nor females disperse at maturity, but instead remain with their mothers in stable matrilineal groups. Genetic data suggest that a similar pattern of natal philopatry may exist among long-finned pilot whales. Sperm whales appear to have a different social structure again. Groups of females and immature males are found in the tropical lower latitudes. Juvenile males remain in these natal groups until they reach puberty, at which stage they depart to lead more solitary lives in colder temperate and polar waters. They later return to the tropics when fully mature and search for estrous females with which to mate. Long-term studies of sperm whales have demonstrated strong cooperative bonds between individuals in groups of females and immature males (Fig. 5). These groups were thought to be composed of matrilineally related individuals; however, evidence suggests that they are not purely matrilineal in structure, but are comprised mainly of clusters of related individuals and also of some animals with no close relations. Baird's beaked whales may have one of the most unusual social systems among odontocetes, although this is inferred only from studies of dead animals. It appears that males mature an average of 4 years earlier than females and may live up to 30 years longer (Kasuya *et al.*, 1997). This has led to speculation that males may be providing significant parental care.

An interesting congruence between low levels of mitochondrial diversity and the presence of matrilineal social systems in four species of odontocete may suggest the cultural transmission of matrilineally inherited traits (Whitehead, 1998). Apparent culture in cetaceans includes the learning of particular feeding techniques from the mother or members of the matrilineal group. In fact, many attributes of cetaceans (and odontocetes in particular) favor the evolution of social learning and culture. These include their long lives (~60 to 90 years), advanced cognitive abilities, prolonged parental care, permanent and cohesive groups, and an environment that varies substantially over large spatial and temporal scales (such that individual learning would be costly) (Whitehead, 1998).

A potential offshoot of the advanced sociality observed in some species of odontocetes is the presence of postreproductive care. Short-finned pilot whales (*Globicephala macrorhynchus*) show a decreasing pregnancy rate with increasing maternal age and a parallel age-related decline in the ovulation rate. Up to 25% of adult females may be postreproductive, ceasing to ovulate after age 40 even though the maximum life span exceeds 60 years (Marsh and Kasuya, 1991). However, lactation may continue for up to 15 years after the birth of their last calf. It is unclear whether communal nursing exists.

TABLE III
Social Strategies Employed by Odontocete Species Known from Long-Term Studies of Wild Animals

Species	*Social group*	*Mating system*
Shark Bay bottlenose dolphin	Male coalitions Female groups	"Capture" of females by a coalition of males
"Resident" killer whales	Matrilineal groups of females and descendents	Intergroup matings thought to occur when groups meet
Sperm whale	Matrilineal groups of females and juvenile males Solitary adult males	Males rove between groups in search of estrus females

Figure 5 *Group of female and immature sperm whales in the Galápagos Islands. Photograph by Sascha K. Hooker.*

Another apparent consequence of the strong social bonds found among odontocetes is the phenomenon of mass stranding (Sergeant, 1982). This tendency for animals to come ashore in groups to die is found only among the most highly social odontocete families. Several explanations for this behavior have been suggested. These include disorientation due to geomagnetic anomalies, panic flight responses from predators, morbillivirus infections, parasitic infections of the respiratory system, brain, or middle ear, or the strong social bonds of a group causing the entire group to follow one intentional strander. It has also been noted that many locations in which mass strandings occur share certain structural characteristics. These sites are often composed of a sandy peninsula or promontory that extends perpendicular to the coastline and appears to form a "whale trap," potentially due to the loss of ECHOLOCATION abilities in the shallow sandy environment.

VII. Mating System, Reproduction, and Life History

Many odontocete species have promiscuous MATING SYSTEMS in which several adult males may mate with a female. However, other species, such as the bottlenose dolphins in Shark Bay and Dall's porpoises, appear to show a form of mate guarding. Among many beaked whale species, males compete, suggesting that there may be a hierarchical nature to their social organization, probably for access to females. However, detailed comparative data on the mating systems of odontocete species await genetic analyses to determine paternity from offspring within groups.

Gestation periods of odontocetes range between 7 and 17 months and almost all species have interbirth intervals of greater than 1 year (Berta and Sumich, 1999; Reynolds and Rommel, 1999). Length of gestation and fetal growth rate are related to calf size at birth such that larger species tend to require longer periods of gestation. Odontocetes produce a single offspring, which is physically well developed (able to swim and surface to breathe) but socially undeveloped. As a result, odontocete species have characteristically long lactation periods, averaging between 32 and 100 weeks (Berta and Sumich, 1999). Females continue to feed throughout this long lactation period.

Odontocetes tend to show extended maternal care, resulting in a strong mother–calf bond. For most species, calves will remain with their mothers for a few years, but for some they will remain in close family groups all their lives (e.g., some killer whale populations, possibly long-finned pilot whales). This high level of investment needed to successfully raise calves may have led to the need to practice mothering behavior. Association between infants and nonmothers, termed allomaternal behavior, has been described for a variety of odontocete cetaceans (Mann *et al.*, 2000). Among bottlenose dolphins, such behavior appears to primarily benefit the nonmother, providing experience in parenting. Similar babysitting has also been documented in sperm whale groups, which stagger their deep-diving behavior such that calves are almost always accompanied by an adult at the surface. However, the function of this behavior in these circumstances appears to relate to increasing calf survival and defense against predation rather than to practice mothering (Mann *et al.*, 2000).

Much of the life history data available for odontocetes has come from studies of dead animals (from those taken in WHALING operations, as bycatch to other fisheries, or from STRANDINGS). The age of an odontocete can be estimated from its teeth using much the same technique as counting the growth rings of a tree trunk. As an individual grows, incremental growth layers are deposited in the teeth and bones. In order to determine the age, the tooth is usually thinly sliced and polished and may often be etched or stained to better resolve the growth layer groups. In most species, each growth layer group is thought to represent an annual increment, but this needs to be verified independently in order to use this method for each species. By establishing the ages of animals, researchers are able to investigate the age structure of the population, to look at ages at which animals mature, reproduce, and so on. Long-term studies of odontocete species in the wild (e.g., those listed in Table III) are gradually allowing life history parameters to be recorded from living animals. In some cases, particularly in establishing life span, these are providing records of life span to a much greater age than were estimated from catch records.

Life histories recorded in this manner show large differences between different odontocete species. Harbor porpoises have a maximum longevity of 12 years (although some may live up to 17 years), they reproduce at age 3, and become pregnant every year thereafter. In contrast, killer whales have a maximum longevity of about 80 years and first give birth at approximately 15 years of age, with a 5-year interbirth interval. Many species also show sex-specific differences in life history parameters. For example, sperm whale females become sexually mature at approximately age 9–10, whereas sperm whale males do not appear to become sexually mature until approximately age 26–27.

VIII. Human Interaction and Conservation Status

In the past, the majority of human interaction with odontocetes involved the capture of animals from the wild, either for consumption as part of the whale industry or, more recently, to obtain animals for captive display purposes. Only a few odon-

tocete species were hunted to the same scale as the fisheries for baleen whales in the last two centuries. The main odontocete species taken historically were the sperm whale, some beaked whale species (northern bottlenose whales and Baird's beaked whales), and pilot whales. However, although the moratorium on large whale hunting essentially put an end to the hunting of mysticetes, the only odontocete species included in this moratorium was the sperm whale. Thus today, many odontocete species are still taken in large numbers. Unfortunately, many of these go unmonitored, and so the exact numbers taken are unknown, although they are suspected to be high.

Several odontocete species are or have been maintained in captivity for display, research, or conservation purposes (Twiss and Reeves, 1999). Some species are maintained in captivity for research or public display (e.g., bottlenose dolphin, killer whale, beluga), whereas others have only rarely been kept in captivity following live stranding (e.g., sperm whales, beaked whales). Some species are bred successfully in captivity, including bottlenose dolphins, Commerson's dolphins (*Cephalorhynchus commersonii*), and killer whales, but most other odontocetes species do not appear to fare so well in captive situations.

Humans are also increasingly attempting to interact with odontocetes in the wild. Whale-watching operations are increasing in number worldwide. In the San Juan Island area between British Columbia, Canada, and the state of Washington, the number of whale-watching vessels has increased 10-fold over the last decade. There is currently a good deal of concern about the impact of whale watching on the animals involved. Although there has been little documentation to date of immediate adverse impacts, there has been little investigation of the long-term stresses and consequences for the viability of the populations concerned. Swim-with-dolphin programs are also increasing in frequency. There is also concern about the effect of these, although one of the most pressing concerns is the potential to wrongly educate the public. As a result of these activities, the general public may form the perception that association with wild animals is endorsed. Currently in Florida, many people continue to solicit interactions with wild dolphins and, despite legislation against it, often encourage this by provisioning.

Lone animals of several odontocete species have, at times, been recorded to solicit associations with humans. This behavior has been recorded a number of times all over the world. In all cases, animals have become resident in a small area, where they approach and interact with boats or people in the water. In many cases, the animals involved have been common bottlenose dolphins, but this behavior has also been recorded from belugas and rough-toothed dolphins (*Steno bredanensis*).

Today, CONSERVATION problems exist for nearly all odontocete species. In fact, since the International Whaling Commission moratorium on catching large whale species, many of the current conservation threats faced by cetaceans are likely greater for odontocete species than for mysticetes. Their typically smaller size means they are less likely to be able to free themselves when trapped in nets, leading to a high incidence of bycatch. The squid diet of many species renders them prone to plastic ingestion, and their higher trophic levels magnify their pollutant load. Additionally, the habitat specificity shown by many species means that they have little recourse in the face of habitat destruction.

Other less direct threats to odontocetes include NOISE and disturbance, POLLUTION, and habitat loss and degradation. In general, noise is thought to be less of a problem for many odontocete species than for mysticetes, as much oceanic anthropogenic noise is low frequency. However, higher frequency noise (such as that created by fish finder units) is likely to coincide with the hearing range of many odontocetes (Twiss and Reeves, 1999). Additionally, some odontocete species (such as sperm whales and beaked whales) are thought to be susceptible to disturbance from low-frequency sounds.

Training

TED TURNER
Behavior International, Aurora, Ohio

Marine mammal training is a relatively new field that gained formal recognition in the late 1940s. One of the first institutions to successfully maintain a breeding colony of BOTTLENOSE DOLPHINS, Marineland of Florida also became the first institution to begin a formal training program for bottlenose dolphins (*Tursiops truncatus*). As behavioral observations of these animals began to generate questions unanswerable through scientific observation alone, it seemed that further exploration involving dolphin-learning abilities could only be facilitated through training. Early training methods were considered industry secrets, yet those techniques were primitive. Although the methods used at that time were limited, consisting of trial and error, the marine mammal training field now employs proven behavior modification principles and, most predominantly, operant conditioning (behavior that is modified by the consequences) as a means to teach various behaviors to marine mammals. While the use of operant conditioning is not the only mechanism used to train marine mammals, it is arguably the most productive. Therefore, the fundamentals of this science must be assimilated in order to be successful at training marine mammals. Because the field of marine mammal training minimizes the use of punishment techniques, it is highly productive and continues to stand as a model for ethical training. The high exposure and excitement that is created when performing for the general public has focused attention on the cognitive abilities of these animals. Although some disagree with the use of animals in show performances, most are fascinated by the level of complexity, coordination, and consistency in behavior. Still others are amazed at the degree of intimacy and interaction between animal and trainer. Magical to some and practical to others, it is the training process itself that creates the medium for "communication" between marine mammal behaviorists and the animals they closely interact with. In most cases, the shows provide the animals with stimulating enrichment and the general public with the motivation for further education (Fig. 1).

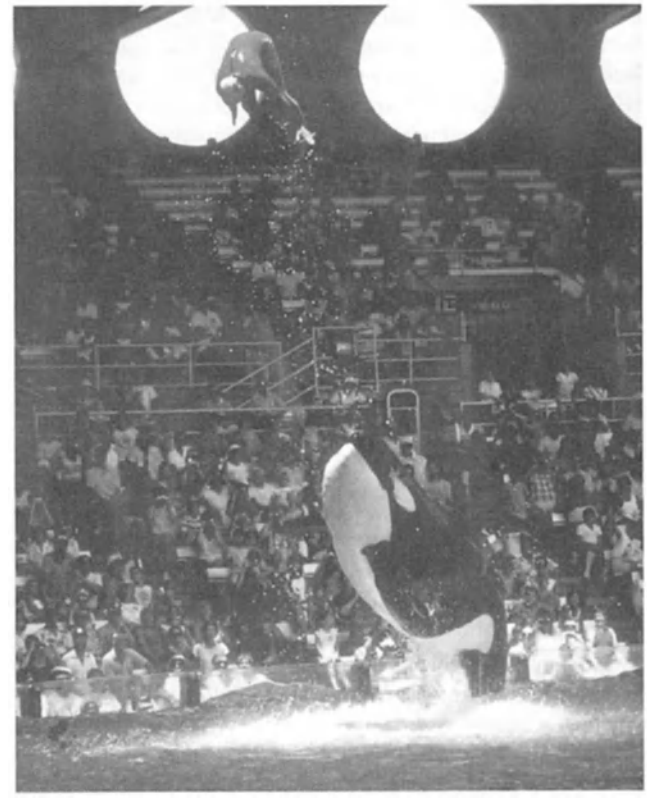

Figure 1 *Marine mammal training and show performances generate public interest in marine mammals and related issues.*

I. Animal Learning and Behavior

Learning is a fundamental biological process necessary for survival. The expression or suppression of certain behaviors enable animals to respond to their environment and adapt to social and environmental changes. The detailed study of animal learning primarily involves aspects of psychology, such as memory, developmental learning, classical conditioning, operant conditioning, behavior modification, cognition, and other information processing disciplines. When describing the main components of current marine mammal training, the following three primary learning modes become salient.

A. Observational Learning

Also known as modeling, this vicarious process is defined as learning by observing another (model) engage in a behavior. During observational learning, the animal (observer) need not emit the observed behavior nor receive direct consequences in order that learning occurs. Mimicry seems to be a by-product of observational learning. It is a primary learning element for young animals raised in a complex social environment and appears to be of significance in developing socialization skills. The expression of these mimicked behaviors is not relegated to social behavior only. Young marine mammals will attempt to mimic trained behaviors and will often accompany adults in show performances or training sessions. It is common practice for marine mammal behaviorists to "capture" (reinforce) mimicked behaviors in order to rapidly develop and accelerate the learning process for young animals. However, regression often occurs when the model (adult) is no longer present. Training programs that rely on observational learning must often retrain these animals using direct operant conditioning and behavior shaping

with individual training sessions. Nonetheless, observational learning plays an important role in the lives of marine mammals.

B. Classical Conditioning

Past understanding of Ivan Pavlov's early work investigating anticipatory salivation in dogs led to a restricted view that classical conditioning [the pairing of a conditioned stimulus (CS) in conjunction with an unconditioned stimulus (UCS)] only produced learning involving reflex systems. In recent years, this view has been replaced with a more contemporary understanding. Associations between conditioned and unconditioned stimuli have been linked to learning phenomena such as sign tracking (movement toward a stimulus that signals the availability of a positive reinforcer such as food), conditioned emotional response (fear), and taste aversion (food preference/avoidance). These seemingly insignificant components have a major impact on subsequent learning during the training process. Accidental pairing of events can create learning via classical conditioning that can interfere with or influence the training of marine mammals. Associating food with a loud noise, for example, can eventually diminish the startle effect the noise might otherwise evoke. However, pairing that same loud noise with a painful medical procedure can exacerbate the negative reaction to that same noise in the future. A minor avoidance response by the animal could intensify into a severe aggressive or panic response, causing injury to the animal or the animal handlers. An experienced marine mammal behaviorist understands this relationship and its effects on the training process. Classical conditioning can be used to help modify behaviors needed for the long-term care of marine mammals, such as introducing new animals into established social groups.

C. Operant Conditioning

Defined as behavior that is modified by its consequences, operant conditioning is currently recognized as the most widely employed training program for marine mammals. The basic components of instrumental learning (learning that occurs as a result of operant conditioning) must occur *in precise order* for learning to be achieved. These three components are the *antecedent* (a stimulus that precedes the behavior), the *behavior* (the resultant observed response emitted by the animal that immediately follows the antecedent), and the *consequence* (a stimulus that immediately follows the response and acts to increase or decrease that behavior). During a training session, a hand signal (antecedent) is usually presented to the animal followed by the animal's response (behavior). If correct, the behavior is usually reinforced (consequence) by the trainer with either primary reinforcement (food) or secondary reinforcement (touch, toys, play, activities). Common in marine mammal training, incorrect behaviors are usually ignored with minimal or no consequence applied. Punishment and negative reinforcement are generally avoided. Other animal training fields use a wide variety of punishment and negative reinforcement techniques to suppress unwanted behavior. In the operant process, each behavior is best described as a learning cycle (Fig. 2).

Principles supporting the successful, technical application of these three elements must be understood by the behaviorist

Figure 2 *A typical operant conditioning cycle where the signal (antecedent) precedes the response (behavior), followed by the reinforcement (consequence). A single training session includes many such cycles.*

and include stimulus consistency, stimulus fading, behavioral criterion, behavioral development, delay of reinforcement, schedule of reinforcement, magnitude of reinforcement, and many others. Successful marine mammal trainers understand the implications of precise application. Like other forms of learning, operant conditioning should not be characterized as a "technique" or "system" of training that can be switched on and off conveniently, instead it is a dynamic and ever present environmental learning phenomena that is in continuous action, influencing the acquisition or extinction of specific behaviors. Behaviors are in the constant process of strengthening or diminishing as a result of the consequences that follow. It must be emphasized that not all of the antecedents and consequences experienced by each animal are applied by the marine mammal trainers. Behaviorism views the environment in its entirety with many such antecedent stimuli being processed by the animals in context. Even in the most productive marine mammal training programs, it is rare that more than 3 hr per day, on average, are devoted to actual training sessions, leaving 21 hr per day to other environmental learning influences. For large institutions with formal marine mammal training programs, certain principles and techniques have been refined and operationalized to facilitate staff development and expertise, resulting in efficient animal training. Expertise is often gained through practical hands-on application and is supplemented with course work, seminars, and testing. Other mediums, such as conference attendance and trade groups, provide additional sources of information. The International Marine Animal Trainers Association (IMATA) is an established trade group that offers opportunities to formally exchange specialized marine animal training information. Many marine mammal training programs usually emphasize the following.

1. Establishing "Trust" As an anthropomorphic expression, the word "trust" is used here to describe a more complex set of behavior. Naïve animals (animals without prior training experience or a limited behavior repertoire) often seem cautious and

wary of their surroundings. This apprehension can be reduced by minimizing or eliminating those practices that create avoidance or fear response, such as rough handling, aversive procedures, and loud noises. The process of extinguishing avoidance behavior is aided by the cumulative, positive effect of daily feedings and time spent with the animal. Within a few days, marine mammals will readily take food from the familiar hand and allow some calm touching during feeding. This provides the foundation for positive reinforcement (a stimulus that is applied as a consequence and increases the frequency, intensity, and duration of the preceding behavior). Regression can be minimized if aversive events can be delayed or eliminated. As a reinforcement history develops, unavoidable aversive events (such as routine medical treatment) have less impact and cause minimal regression. The opposite appears to be true as well. Repeated aversive procedures early in the process can have a profound negative effect and will delay the positive response to the trainer.

2. *Conditioned Reinforcer* The consistent pairing of a stimulus with the applied reinforcer (initially food) establishes the foundation for a conditioned reinforcer (a stimulus that has acquired reinforcing properties through learning). Most marine mammal training facilities call this a "bridging" stimulus. This bridging stimulus acts as a cue that signals the application of reinforcement (a stimulus that increases the frequency, intensity, and duration of a preceding behavior). It is referred to as a "bridge" because it acts to bridge the time delay between the precise behavior targeted for increase and the positive reinforcement. Marine mammal trainers and behaviorists use a variety of tools that act as a bridge. Typically, a high-frequency whistle is used for cetaceans (due in most part to higher hearing ranges), whereas a verbal cue or clicker sound is used for other marine mammals. This bridging stimulus, when paired consistently with the offering of food, quickly becomes recognized by the animal. Soon the sound itself evokes a response and subsequent orientation back to the trainer.

3. *Building the Attention Threshold* In order to maintain the animal's attention sufficient to advance learning, an early emphasis on attention threshold (the duration that a stimulus will control behavior) is necessary. This is done by systematically increasing the amount of time the animal will continue to watch the trainer prior to bridging and reinforcement delivery. Increments of a few seconds are literally counted by the trainer when shaping an increased attention span. Eventually, within a few days or weeks, an attention span of several minutes can be conditioned if bridging/reinforcement is precise. Conversely, a lack of precision can delay progress. Inexperienced or impatient marine mammal trainers often overlook this critical element.

4. *Following a Target* If the pairing of food with the bridge has been well timed and effective, the animal will quickly learn to touch a hand prior to the bridge and food delivery. By holding the hand close to the animal, the animal will, in all likelihood, touch the hand. The behavior of touching should be reinforced. Eventually, the hand can be moved back and forth in order to strengthen the "following" response. In time, the animal will move to the hand wherever it is. Target poles (a long pole with a small round float attached to the end) are often introduced at this stage to simulate an extended reach. Through the use of this target pole, touching and following can be reinforced. Various behaviors can now be shaped through approximations (Fig. 3).

5. *Achieving Stimulus Control* As animals begin to learn the relationship between their emitted response (behavior) and the delivery of reinforcement by the trainer (consequence),

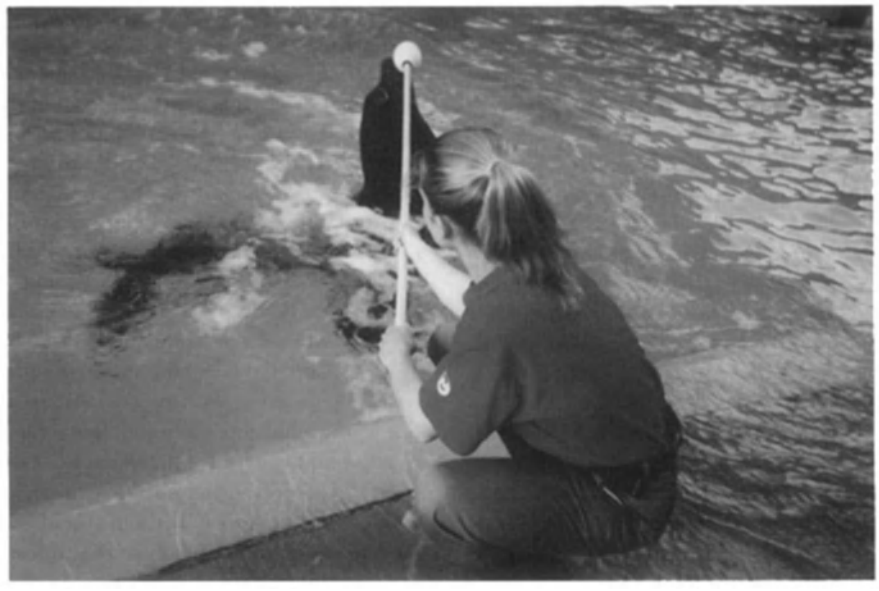

Figure 3 *A California sea lion* (Zalophus californianus) *is trained to follow a target pole. The target enables the trainer to shape behaviors from a distance.*

they also begin to learn which specific behavior will be actually reinforced. Discrimination between learning events occurs when animals learn to respond differently to differing signals (antecedent). The trainer offers reinforcement only for specific responses and thereby facilitates discrimination. This process is aided through the use of specific hand signals (discriminative stimuli) that precede each behavior. When trainers selectively reinforce only desired behaviors, animals learn to recognize the signals and respond appropriately. This is referred to as stimulus control where behaviors are reinforced in the presence of a particular signal or stimulus. Random sampling (performing several behaviors in an attempt to gain access to reinforcement) is a common phenomenon early in the training process. Trainers will ignore all but the requested behavior, thereby aiding the process of stimulus control and discrimination learning.

6. Successive Approximations Effective trainers break each behavior down into small, easily understood and planned steps. For example, a high jump begins with the lifting of the head in order to touch the target pole and receive reinforcement. With each successive approximation, the target is raised slightly until the desired height is achieved. In effect, each behavior can be visualized by the trainer as a step-by-step process. All behaviors can be broken down in such a manner creating an easier learning process for the animal (Fig. 4).

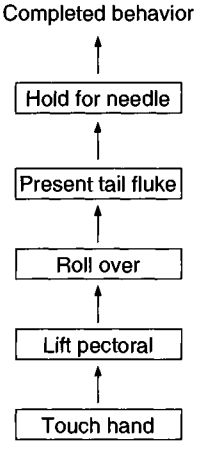

Figure 4 *An approximation diagram of a voluntary blood sampling behavior. Approximations can best be described as small "steps" toward a desired goal. Each step represents an advancing behavioral criterion progressing toward the completed behavior. Here, a dolphin is first conditioned to allow a touch of the pectoral flipper. As this behavior is reinforced, the animal learns to follow the trainer's hand with its pectoral flipper into a roll-over behavior. The roll-over behavior is then reinforced, and the animal learns to present itself in a belly-up position after a few trials. At this point, the trainer begins to reinforce the animal for allowing contact systematically closer to the tail flukes. After a few training sessions, the flukes can be held while a needle is slowly inserted for blood removal from a near surface vein. The trainer delivers reinforcement if the animal remains calm and motionless.*

7. Schedules of Reinforcement This refers to the timing and frequency of reinforcement. As mentioned previously, most all marine mammal training programs emphasize positive reinforcement and generally avoid negative reinforcement (an increase in a response that causes the removal of an aversive stimulus) and punishment (a decrease in a response that is followed by an aversive stimulus). In fact, many marine mammal institutions now consider punishment unethical. Even so, an emphasis on positive reinforcement without regard to the precise schedule of reinforcement can lead to training and subsequent learning problems. Schedules of reinforcement have been derived empirically with many variations currently being studied. Each specific schedule has been shown to manifest certain behavioral characteristics. For example, a simple fixed ratio schedule (where a fixed number of responses is required for reinforcement) can create predictability in the environment and will manifest in episodic motivation with periods of poor response. These behavioral pitfalls are avoided when behavior programs include staff training on the most effective use of reinforcement. It would be an oversimplification to describe the most effective schedule of reinforcement, as each can be equally effective depending on the learning stage of the animal. In general, however, many applied marine mammal training programs are beginning to recognize the importance of variable schedules of reinforcement, including reinforcement variety. Variable schedules of reinforcement provide reinforcement intermittently and unpredictably. This more closely replicates the type of reinforcement schedule most often associated with the wild environment. The challenge of failing and then obtaining primary reinforcement (that which does not depend on learning such as food and water) and secondary reinforcement (an event that becomes reinforcing through learning such as play, games, toys) activates cognition and problem solving. This, in turn, provides enrichment opportunities for each animal while it shapes stronger foraging and hunting skills. (Clearly, it seems logical that an animal that learns to preserve after failure might have a higher survival rate in the wild.) Reinforcement variety (the random delivery of both primary and secondary reinforcement) augments the elements of surprise—an essential component of effective reinforcement.

As mentioned previously, only certain components of operant conditioning have been briefly described for the purpose of identifying those elements that influence the acquisition of trained behaviors most rapidly. Even those institutions that ignore or minimize the use of "training" are most certainly creating positive and negative consequences for behaviors. Formally applied or not, the process of "training" through both operant and classical conditioning continues for the animals. Consider the normal operation of daily cleaning, feeding, and watering. These activities can effectively act as consequences that shape and modify behaviors. The appearance of a cleaning hose, for example, might act as a punisher for certain animals, thereby suppressing the behavior of courtship (depending on the timing of its appearance). However, it could also act as a reinforcer for a different animal, thereby increasing the behavior of vocalizing (again dependent on the timing of appearance). Even stereotypic patterns, such as anticipatory pacing prior to feeding time, create an opportunity for adventitious

reinforcement (coincidental cause and effect reinforcement causing an inadvertent increase in the unwanted behavior). Awareness of these learning principles enables caretakers, behaviorists, scientists, and trainers to better understand *all* environmental factors influencing the expression of appropriate or inappropriate behaviors. As we continue to learn about information processing and training, much more needs to be assimilated by the behaviorist. Memory retrieval, short- and long-term memory capacities, can influence behavior acquisition, especially in higher order animals. Learning phenomena such as context-specific learning (learning in one environment that does not necessarily transfer to another environment) can affect the outcome of a reintroduction project, for example. Further investigations into animal emotion and cognition will add enormously to our understanding of animals as will further studies to determine stage-developmental learning.

II. Early Development and Learning

During the first few days of life, the primary challenge for newborns is maternal acceptance. It seems that a mother's instinctive epimeletic (caregiving) behavior patterns should engage automatically after birth, yet newborns are sometimes rejected and thus are unable to survive. Still others have been injured and even killed by their mothers. This disturbing pattern, although rare, has also been observed in most mammal species (both wild and captive animals), including humans. The wide majority of newborns, however, *are* accepted (some immediately after birth and some within a few hours) and their mothers usually allow them to nurse within 24 hr. On rare occasion, offspring have gone 48 hr without taking their first milk. Within a few days, the calf or pup rapidly acquires the motor skills necessary to coordinate successful nursing while its mother is also acquiring and strengthening her own epimeletic repertoire, thereby increasing survivability in subsequent offspring. For the newborn, motor skill development occurs rapidly and, within a few weeks, observations of increasing independence (time and distance away from the mother) begin to emerge as coordination, buoyancy control, visual acuity, ECHOLOCATION, and auditory learning strengthen. Observational learning becomes evident and mimicry increases until the young animal learns to directly manipulate its environment (Fig. 5).

In some cetaceans, between 4 and 7 months of age when teeth begin to erupt and grow, the mother initiates a weaning process through food sharing (either partially digested and regurgitated or with food that has been ripped into small pieces). This seems to coincide with accelerated learning and may signal the beginning of a sensitive learning phase or critical period (a period of rapid acquisition of behaviors). For marine mammals born in captivity, most formal training begins during this stage.

III. An Emphasis on Positive Reinforcement

Marine mammals respond readily to operant conditioning, probably the most widely used training process, and possess a strong aptitude for instrumental learning. The rapid acquisition of behaviors has done little to refute the notion that marine mammals are unusually "intelligent." It must be stated, however, that other animals trained via operant conditioning sometimes show an equal or superior aptitude and learning curve. As stated previously, most marine mammal training programs restrict the use of punishment and applied negative consequences. Instead, they rely heavily on positive reinforcement. Empirical

Figure 5 *Young animals often learn through observation. Here, a killer whale* (Orcinus orca) *calf is observing as her mother interacts with a trainer.*

evidence suggests that positive reinforcement has a much greater influence in motivating animals to voluntarily engage in behaviors, whereas punishment suppresses the expression of behavior. Additionally, punishment serves to increase the development of undesirable behaviors, such as anxiety, escape, active and passive avoidance, frustration, aggression, and learned helplessness (a state of "giving up"). Training programs that use punishment must increase the frequency, intensity, or duration of the punishment in order to maintain its effectiveness. In time, these types of animal training programs develop animals with significant behavioral difficulties, increased stress, and a loss of motivation. The most effective training process develops a foundation of trust through daily care with the elimination of punishment. Most importantly, the desired outcome is *voluntary cooperation* as opposed to compliance under the threat of retaliation. This, at once, seems the most simple and the most difficult concept for the layperson to grasp. However, it may be the marine mammal training industry's most profound contribution to the social sciences.

IV. Animal Acclimation

The assumption that animals will immediately behave toward a new member with acceptance or at best indifference is often erroneous. Animals use AGGRESSION as a means to acquire and establish territories, food sources, breeding rights, sleeping space, and more. Without employment of simple learning principles, the likelihood of any new member being challenged and subject to aggression is highly likely. In a zoologically controlled environment, this is not often desired but can be mediated successfully via training. The use of classical conditioning has shown promise in animal introductions and acclimation. The initial pairing of each new member (CS) with food reinforcement (UCS) helps counter the perception of the new member being a threat. Additionally, after the initial introduction, the use of an operant technique known as differential reinforcement of other behavior (DRO) provides reinforcement to the group for nonaggression. DRO is a decrease procedure that can target antisocial aggression by increasing prosocial behavior. By combining the learning principles of classical conditioning and operant conditioning, animal acclimation can be facilitated.

V. Husbandry Training

Significant achievements in veterinary care have been achieved through husbandry training. Husbandry training generally consists of the development of a behavioral repertoire that facilitates veterinary access without the use of restraint, anesthesia, or isolation. Optimal animal health is achieved by routine examinations. For an untrained marine mammal, simple procedures and checkups can be a risk to both people and animals. Untrained animals usually express fear, apprehension, and a "fight or flight" response (activation syndrome) that can be dangerous for all involved. Since the early 1990s, a variety of procedures have been routinely trained through operant conditioning, approximation training, and positive reinforcement. A sample of these commonly trained and voluntary behaviors include blood sampling, urine collection, body cavity cultures, eye examinations, topical treatments, injections, x rays, tooth drilling, heart monitoring, body weights, stretcher conditioning, artificial insemination, and gastric intubation.

Once believed impossible to obtain without restraint or anesthesia, routine access to biological samples and simple medical procedures is becoming more and more commonplace in the marine mammal training field which contributes to increased life expectancies. Through training, marine mammal medicine is reaping tremendous benefit from behavioral management. Many zoos are now emulating the success of marine mammal husbandry training and are beginning to experience those benefits with endangered exotic animals as well.

VI. Enrichment and Variety

As we recognize the importance of play in animal development, we have also recognized how important other physical and cognitive challenges are for optimal animal care. An emphasis on behavioral expression pioneered by marine mammal training has gained wide acceptance in zoos, aquariums, and other animal facilities. In the past, this aspect was considered superfluous to animal health and exhibitry. It was believed that "natural" behaviors would be an automatic by-product of a "natural" exhibit. It was soon recognized that these behaviors required more than high-quality food, health care, and housing. A focus on animal enrichment (the application of environmental complexity to stimulate physical activity) has become a necessary component in primary animal care and clearly fits in with the animal training model (i.e., behaviors can be shaped, maintained, and modified using operant techniques). In fact, many successful enrichment programs are managed by experienced animal trainers. They coordinate environmental change, food placement, toys, games, and other behavioral prompts and reinforcers with enormous benefit to the animals. Daily variety and reinforcement of appropriate behaviors help reduce other inappropriate behaviors such as aggression, stereotypic patterns, and stress-related problems.

VII. Long-Term Behavior Management

Applications for marine mammal training principles are expanding into areas traditionally relegated to population management. California sea lions can be extremely aggressive and territorial during the spring and early summer breeding season. Adult males can gain weight rapidly under the influence of increased testosterone production. In zoological settings, the need to replicate this important annual biological cycle serves no purpose for males that are not part of a breeding program and can be problematic. Unless a facility has unlimited space for housing disputing males, intervention must occur to minimize aggression. Current management methods utilize surgical and pharmacological interventions. Progress in behavioral management has proven effective as well. Minimizing body weight fluctuations, paired with direct reinforcement of nonaggression, has been effective. Body weight maintenance requires the training of separation behaviors (separating in and out of a larger group) and daily weight scale readings (the animal is trained to walk onto a platform scale and sit still). The use of DRO decreases inappropriate aggression by increasing behaviors other than aggression.

VIII. Other Uses for Marine Mammal Training

A wide variety of training applications are now being explored in the marine mammal field. In time, these advancements will have as much or more impact than the behavioral advancements preceding these applications. Related to husbandry training, the field of behavior medicine is growing in understanding and in effective use. Behavior medicine (also referred to as health psychology) employs the use of behavior modification to treat chronic and acute medical conditions. Pretreatment baseline data are gathered prior to training (treatment) and subsequent health improvement. A successful treatment model is shown in Fig. 6.

Chronic medical conditions can also be treated by engineering a behavioral training program that targets a specific behavioral goal. All behaviors used for treatment are shaped, trained, and maintained as most other behaviors, although, like traditional medicine, not all treatments are completely successful. A good animal health program utilizes all available expertise, including training (Fig. 7).

Marine mammal training has been employed successfully in open ocean work. The U.S. Navy's marine mammal program has trained a number of marine mammal species a variety of tasks involved in aiding military operations, rescue and recovery, deep diving physiology, echolocation, boat following, and object retrievals to name just a few. These early and ongoing programs continue to generate enormous benefit to scientists in understanding marine mammal learning capabilities, physiology, and motivation. A number of research institutions now use open-ocean training to study certain aspects of marine mammals. Interactive programs that allow in-water interaction are gaining popularity. These high-quality education programs enhance the enrichment that animals receive while giving the general public a chance to get in the water and directly experience the animal's behavioral capabilities. Training techniques have also been employed in the rehabilitation process for sick and injured wild animals. As behavior modification gains wider application, wildlife managers will continue to increase their knowledge and application of these learning principles. Solutions to human/animal encounters, survival skills acquisition for release of captive-born animals into the wild, and behavior problems associated with reintroduction and relocation efforts will require a specialized understanding of the learning and training processes, pioneered in the learning laboratories and practiced in the field of marine mammal training.

Tucuxi

Sotalia fluviatilis

PAULO A. C. FLORES
PUCRS (Pontifícia Universidade Católico do Rio Grande do Sol), Porto Alegre, Brazil

The tucuxi is listed as insufficiently known by the World Conservation Union (IUCN). Most information on the species comes from specimens collected throughout the Amazon Basin; the scarcity of data on the coastal tucuxi is a result of the lack of long-term longitudinal studies of living animals. The scenario has changed since the early and mid 1990's, mostly through research conducted off Brazil. However, few of these studies' results have been published and so far only presented to scientific conferences and conservation meetings and in academic theses. This article intends to include all available information to provide the best overview of the species.

I. Common Names, Distribution, and General Description

The name tucuxi comes from *tucuchi-una* after the Tupi language of the Mayanas Indians from the Amazon region in Brazil. Other names include boto, boto comum, and golfinho cinza along the Brazilian coast; bufeo gris, bufeo blanco, or bufeo negro in Colombia and Peru; lam in Nicaragua; and gray river dolphin in English. Although up to five species and three subspecies were described, today a single species, *Sotalia fluviatilis,* is recognized, presenting two ecotypes, riverine (or freshwater) and marine, which differ somewhat in length, number of teeth, and color pattern. The riverine tucuxi occurs in the Amazon River basin (drainage) including Brazil and going as far inland as southeastern Colombia, eastern Ecuador, and northeastern Peru. The marine tucuxi is found in the western Atlantic coastal waters of South and Central America from southern Brazil (27°35'S, 48°35'W) to Nicaragua (14°35'N, 83°14'W), including Colombia, Costa Rica, French Guyana, Guyana, Panama, Suriname, Trinidad, and Venezuela, with possible records to Honduras (15°58'N, 79°54'W). In the Orinoco River the species may be seen as far up as Ciudad Bolivar, although whether these specimens belong to the riverine or marine ecotype is not clear. No fossil record is known so far.

The tucuxi looks somewhat like a smaller bottlenose dolphin, *Tursiops truncatus.* It is light gray to bluish gray on the back and pinkish to light gray on the ventral region, with a distinct boundary from the mouth gape to the flipper's leading edge. On the sides the tucuxi has a lighter area between the flippers and the dorsal fin and another one in the midbody at the anus level; marine individuals may have another light gray rounded streak on both sides of the caudal peduncle. The eyes are large, and around the eyelids there are black countershadings. The dorsal fin is triangular and sometimes slightly hooked at the tip (Fig. 1). It has a moderately slender long beak, a rounded melon, and 26 to 36 teeth in each mandibular ramus. The marine tucuxi has more upper teeth and is larger than riverine specimens: total length can reach about 210 cm (with an extreme 220 cm reported) in the marine and about 152 cm in the riverine ecotype.

II. Ecology and Behavior

The marine tucuxi is found mostly in estuaries, bays, and other protected shallow coastal waters. It feeds mainly on demersal and pelagic fishes such as clupeids and scianids, and neritic cephalopods, shrimps, and flounders are occasionally taken. The riverine *S. fluviatilis* occurs in the main channel of rivers, tributaries, and lakes, usually avoiding rapids and not going into the flooded forest as the sympatric boto *Inia geoffrensis.* Its movements may be influenced by seasonal level fluctuation, using channels and lakes during rising and high waters while avoiding them during the low-water season.

Potential predators are the killer whale *Orcinus orca* and various species of coastal sharks for the marine ecotype and the bull shark *Carcharhinus leucas* in the Amazon. However, no record of such predation is known so far.

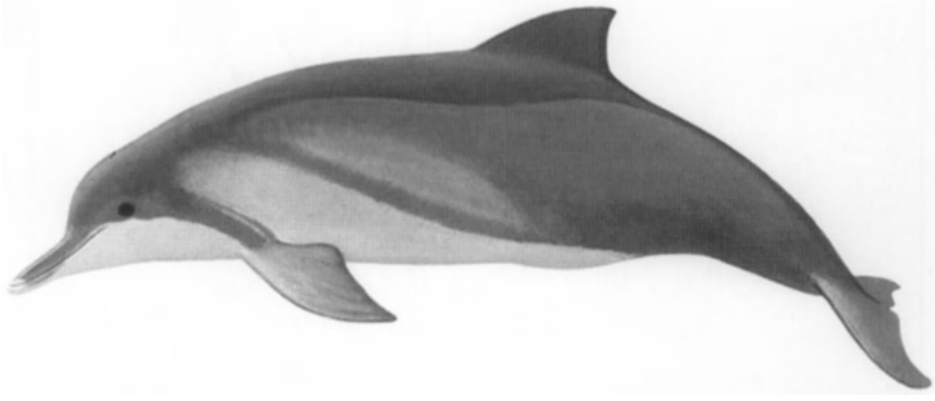

Figure 1 *Relatively little has been published concerning the Amazon dolphin called the tucuxi, which tends to occupy estuary and other shallow coastal habitats. Pieter A. Folkens/ Higher Porpoise DG.*

The tucuxi is a social dolphin often found in groups of 2 to 6 individuals. Groups of up to 50 or 60 specimens of the marine ecotype can usually be found. Large aggregations of up to 200 are reported in Baía de Sepetiba and around 400 individuals in Baía da Ilha Grande (Lodi and Hetzel 1998), on the southeastern Brazilian coast. Larger aggregations are usually engaged in cooperative feeding. Feeding occurs roughly in two ways: in pairs and cooperatively in larger groups or subgroups when different strategies are employed. During feeding activities marine tucuxis often associate with birds such as the brown booby *Sula leucogaster*, terns (*Sterna* spp.), frigate *Fregata magnificens*, and kelp gull *Larus dominicanus*. In some locations, mixed flocks of up to 100 birds can be seen in such associations. In the Amazon, the tucuxi may feed occasionally in association with terns (*Phaetusa simplex*).

The presence of the tucuxi is recorded throughout the year in many coastal locations such as Baía Norte (South Brazil, coinciding with the species southernmost distribution limit), Cananéia estuary and Baía de Guanabara (both in southeastern Brazil), Baía de Todos os Santos, and around Fortaleza (northeastern Brazil), as well as Bahia Cispatá and Golfo de Morrosquillo (Colombia). Photoidentification studies in few of these areas have demonstrated that at least some animals are resident year-round for up to 7 continuous years (e.g., Flores 1999; Flores *et al.*, 1999). The riverine tucuxi is very common in the Solimões River and its tributaries as well as the Mamirauá area (Brazil), the Tarapoto River as well as Caballococha and El Correo lake systems (Colombia), and near Iquitos (Peru), to give some examples (Fig. 2). From scarce available data, abundance estimations in an area vary with the method employed. In Baía de Guanabara, it was calculated at between 69 and 75 individuals through photoidentification (Pizzorno, 1999) to 418 animals by line transect methods (Geise, 1991). It seems that the marine tucuxi is common but not numerous in such areas. In at least some locations the riverine ecotype is found in one of the highest densities found for cetaceans (Vidal *et al.*, 1997).

Figure 2 *Map of tucuxi distribution.*

Dive times are about 1.5 to 2 min with shorter surfacings every 5–10 sec in between. A variety of aerial behaviors may be displayed, such as full leaps, somersaults, flukes-up, spy-hopping, surface rolling, and porpoising. They do not bow ride but may surf in waves or wakes produced by passing boats. A lone, wild, and sociable animal, as well as a case of epimeletic behavior, was recorded along the São Paulo coast in southeastern Brazil. Tucuxis may interact with bottlenose (*Tursiops truncatus*) and Amazon river (*Inia geoffrensis*) dolphins. They have been engaged in apparent mating behavior with bottlenose dolphins off Costa Rica.

No mass stranding has been recorded, although dead animals usually wash ashore along its distribution, mainly resulting from INCIDENTAL CAPTURE in fisheries.

III. Natural History

The breeding system of the species is polyandrous, with mating involving tactile contact and copulation occurring belly to belly. Calving is year-round in most of the coastal species' distribution and in October–November during low-water season for the freshwater ecotype. Gestation is estimated to be around 11 to 12 months with calves ranging from 90 to 100 cm (marine ecotype) and around 10 months and 71 to 83 cm (riverine ecotype). The calving interval is believed to be 22–23 months (through photoidentification data). According to tooth growth layer groups, the lifespan can reach 30 and 35 years for marine and riverine ecotypes, respectively. Natural mortality rates are unknown.

IV. Interactions with Humans: Threats and Conservation

The species have not been exploited commercially, although incidental mortality in local and commercial fishing gear such as gill nets and seines are the main direct threat to tucuxis. In some localities they are killed on occasion for shark bait or human consumption, although tucuxis have protection from myths and legends, especially in the Amazon. There, their genital organs and eyes have a small market as love charms. Dams and hydroelectric power facilities may isolate populations and interrupt fish migration as well as reduce fish abundance. Gold mining with mercury, destruction of mangroves and salt marshes, water pollution, and boat traffic are other potential threats. The recent events of hand feeding and the short-term behavioral effects caused by tourism boats also deserve concern.

Tucuxis die easily due to capture stress during transportation or handling. Some animals, though, have been held in captivity, where they exhibit rare aerial behavior and common aggression toward male tucuxis and other species. Today just a few tucuxis are kept in European facilities.

Tuna–Dolphin Issue

TIMOTHY GERRODETTE
Southwest Fisheries Science Center, La Jolla, California

I. The Problem

In the tropical waters of the Pacific Ocean west of Mexico and Central America, large yellowfin tuna (*Thunnus albacares*) swim together with several species of dolphins (pantropical spotted, *Stenella attenuata;* spinner, *S. longirostris;* and short-beaked common, *Delphinus delphis*). This ecological association of tuna and dolphins is not clearly understood, but it has had two important practical consequences: it has formed the basis of a successful tuna fishery and it has resulted in the deaths of a large number of dolphins. This is the heart of the tuna–dolphin issue.

The bycatch of dolphins in the eastern tropical Pacific (ETP) purse seine tuna fishery stands apart from marine mammal bycatch in other fisheries, not only in scale but in the way the

dolphins interact with the fishery. Marine mammals interact with most fishing gear only incidentally, but in the ETP tuna fishery the dolphins are an intrinsic part of the fishing operation. The fishermen intentionally capture both tuna and dolphins together and then release the dolphins from the net. The vast majority (more than 99%) of dolphins captured by the ETP tuna fishery are released alive; thus, an individual dolphin may be chased, captured, and released many times during its lifetime.

The number of dolphins killed since the fishery began some four decades ago is estimated to be over 6 million, the highest known for any fishery. For comparison, the total number of whales of all species killed during commercial whaling in the 20th century is about 2 million. In recent years, the killing of dolphins in the ETP tuna fishery has declined by two orders of magnitude, but even at this level it remains one of the largest documented cetacean kills in the world.

II. Purse Seining for Tuna

Prior to the development of modern purse seines, tropical tuna were caught one at a time using pole-and-line methods. In the late 1950s the twin technological developments of synthetic netting that would not rot in tropical water and a hydraulically driven power block to haul the net made it possible to deploy very large purse seine nets around entire schools of tuna, and thus to catch many tons of fish at a time. Purse seining for tuna in the ETP can be conducted in one of three ways: the net may be set around schools of tuna associated with dolphins ("dolphin sets," which catch large yellowfin tuna), around schools of tuna associated with logs or other floating objects ("log sets," which catch mainly skipjack but also bigeye and small yellowfin tuna), or around unassociated schools of tuna ("school sets," which catch small yellowfin and skipjack tuna). The proportion of each set type has varied considerably, but during the past decade, dolphin and school sets have been roughly equal in number (about 45% of the 15,000–20,000 sets each year), and the remainder (about 10%) have been log sets.

Dolphins are killed almost exclusively in dolphin sets. During "porpoise fishing" (the fishermen's term), schools of tuna are located by first spotting the dolphins or the seabird flocks that are also associated with the fish. Speedboats are used to chase down the dolphins, herd them into a tight group, and set the net around them (Fig. 1). The tuna–dolphin bond is so strong that the tuna stay with the dolphins during this process, and thus tuna and dolphins are captured together in the net (Fig. 2). Dolphins are released from the net during the backdown procedure (Fig. 3). If all goes well, the dolphins are released alive, but the process requires skill by the captain and crew, proper operation of gear, and conducive wind and sea conditions. As with any complicated procedure at sea, things can go wrong, and when they do, dolphins may be killed.

The bycatch in log and school sets is larger than in dolphin sets, but consists primarily of other fish, not dolphins. While the effects of the fishery on dolphin populations have been strong and are relatively well known, the effects on other marine populations of concern, such as sharks and sea turtles, are unknown.

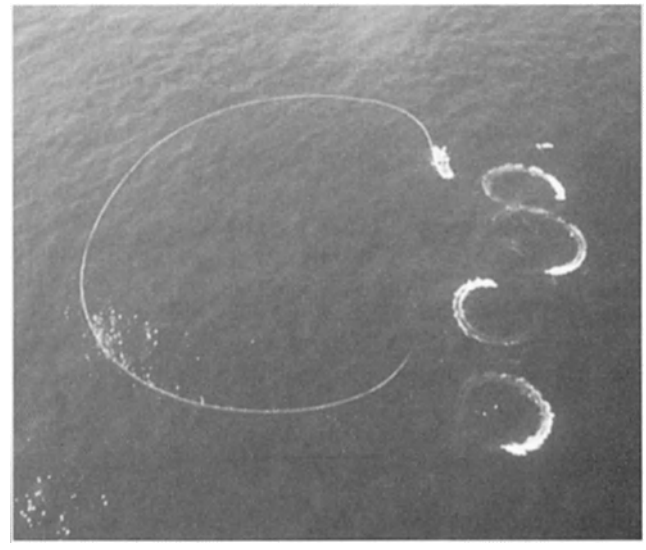

Figure 1 *Purse seine being set on tuna and dolphins in the eastern tropical Pacific Ocean. The net is not yet closed, and four speedboats are driving in tight circles near the opening to keep the dolphins from escaping.*

III. Actions to Reduce Dolphin Bycatch

The magnitude of dolphin mortality in the ETP tuna fishery first came to widespread attention in the mid-1960s. The dolphin kill at that time is not known with precision, but without question was very high (Fig. 4). When the U.S. Marine Mammal Protection Act was passed in 1972, it included provisions for reducing the bycatch to "insignificant levels approaching zero" after a moratorium on regulation during which the tuna industry was expected to solve the problem through the development of improved fishing methods. Under this law, scientific studies were initiated, observers were placed on fishing boats, fishing gear was inspected, and boat captains with high dolphin mortality rates were reviewed. Modifications of fishing gear and procedures were developed to reduce dolphin kill. After much litigation, the first regulations to reduce the dolphin kill on U.S. vessels were promulgated. By the end of the 1970s, the kill had declined from about 500,000 to about 20,000 dolphins per year (Fig. 4).

As the U.S. tuna fleet decreased in size and the fleets of Mexico, Venezuela, Ecuador, and other Latin American countries increased, the dolphin kill began to grow again, and actions to monitor and reduce the dolphin bycatch became international. The Inter-American Tropical Tuna Commission began a dolphin conservation program in 1979 modeled on the U.S. effort. By 1986, an international observer program with all countries participating showed that total dolphin mortality had increased to 133,000/year (Fig. 4). Because U.S. boats operated under restrictions that did not apply to boats of other countries, the United States began requiring that imported tuna be caught at dolphin mortality rates comparable to U.S. boats. The concept of dolphin-safe tuna—tuna caught without

Figure 2 *Spotted dolphins in a purse seine net waiting to be released. Photo by W. High, courtesy of National Marine Fisheries Service.*

setting on dolphins (i.e., log and school sets)—became popular, and by 1994 only dolphin-safe tuna could be sold in the United States. These trade actions were important because the United States is the largest market of the canned tuna product of the fishery.

The dolphin kill declined between 1986 and 1993 due to these various political and economic pressures (Fig. 4). Starting in 1993, the ETP fishing countries voluntarily agreed to increased observer coverage, skipper review panels, and a schedule of decreasing dolphin quotas on an individual boat basis (the La Jolla agreement). The Declaration of Panama of 1995 carried these ideas further, proposing observers on every boat over 400 tons and strict per-stock dolphin mortality limits. These features became part of the International Dolphin Conservation Program Agreement, a binding document among the major fishing countries that went into force in 1999. By this time total reported dolphin mortality had fallen to fewer than 3000 dolphins/year (Fig. 4).

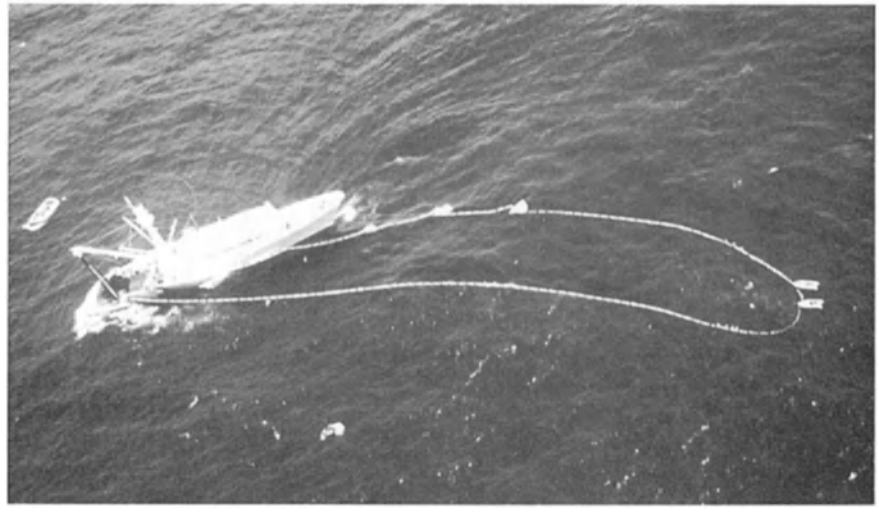

Figure 3 *Backdown procedure in progress. As the tuna vessel moves backward, the net is drawn into a long channel. The corkline at the far end is pulled underwater slightly, and the dolphins escape. Speedboats are positioned along the corkline to help keep the net open.*

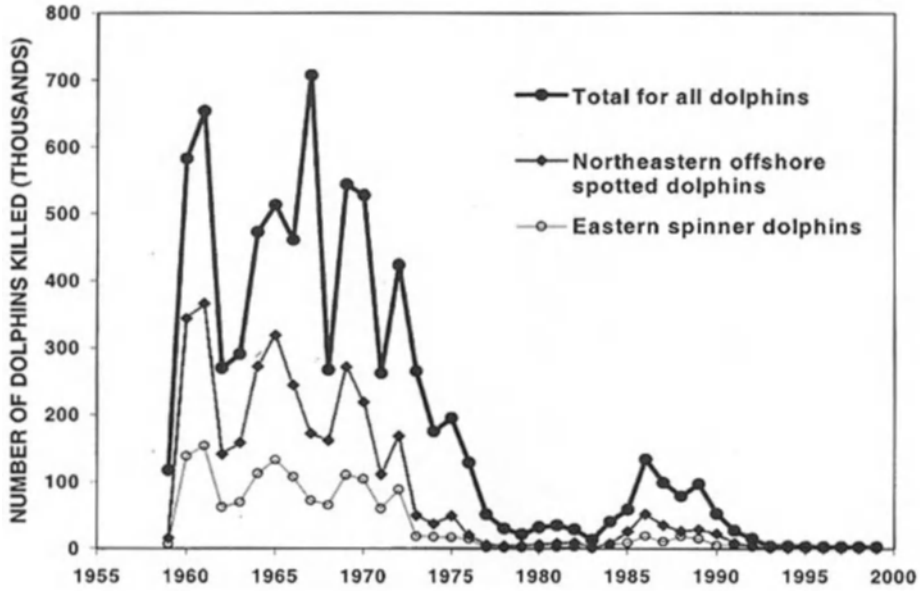

Figure 4 *Estimated annual number of dolphins killed (all dolphins and two dolphin stocks with the highest number killed) in the eastern tropical Pacific purse seine tuna fishery.*

The Declaration of Panama also called for the United States to change its definition of dolphin-safe tuna to include tuna caught by setting on dolphins as long as no dolphins were observed killed or seriously injured *on that set*. Before changing the dolphin-safe label, however, the United States undertook studies to determine if the process of chasing and encircling dolphins was having a significant adverse impact on depleted dolphin populations. At the time of this writing these studies were underway.

IV. Status of Dolphin Populations

The status of ETP dolphin stocks (management units) is based on three time series of data: estimates of the number of dolphins killed, estimates of ABUNDANCE from dedicated research vessel surveys, and estimates of an index of abundance from sightings on tuna vessels. Combining these data in a population model has indicated that the stocks most affected by the tuna fishery are the northeastern stock of the offshore pantropical spotted dolphin (*S. attenuata*) and the ETP

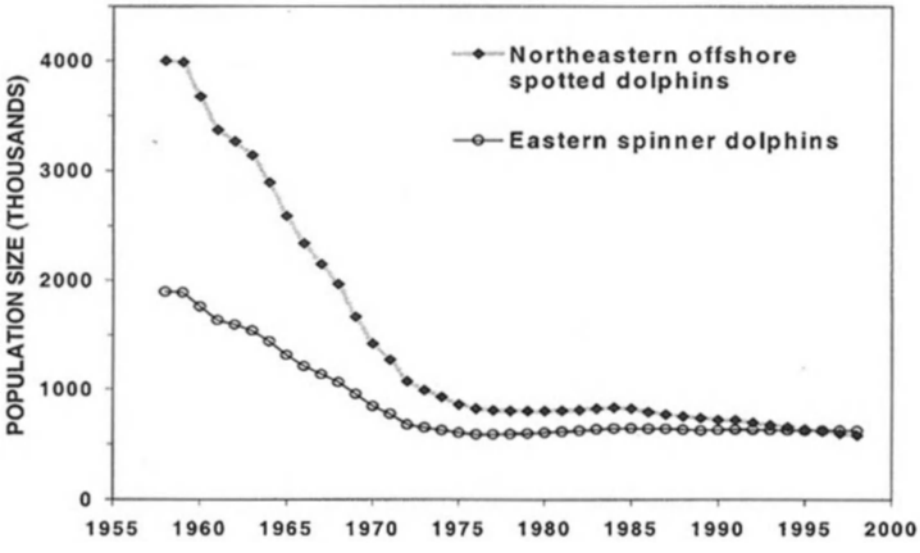

Figure 5 *Estimated population trajectories of northeastern offshore spotted dolphins and eastern spinner dolphins in the eastern tropical Pacific Ocean. The populations declined due to the high number of dolphins killed in the tuna fishery from 1960 to 1975.*

endemic subspecies, the eastern spinner dolphin (*S. longirostris orientalis*). Both populations declined between 1960 and 1975 (Fig. 5), during the period of high mortality on U.S. boats (Fig. 4), but have remained approximately constant since then. As of 1998, northeastern spotted and eastern spinner dolphins were estimated to be at 15 and 34%, respectively, of population sizes when the fishery began. Other stocks have apparently been less affected, although little is known of the small populations of coastal forms of spotted and spinner dolphins.

Since 1993, reported dolphin mortality has been a very small fraction of population size so that recovery of the dolphin populations was expected. By 1999, however, there was no clear indication of a recovery for either northeastern offshore spotted or eastern spinner dolphins (Fig. 5). Several hypotheses could explain these apparent failures to recover: cryptic effects of repeated chase and encirclement on survival and/or reproduction (internal injuries, stress, hyperthermia), separation of nursing calves from their mothers during the fishing process, unobserved or observed but unreported mortality, effects due to breakup of dolphin schools (increased predation, social disruption), ecological effects due to removing tuna from the tuna–dolphin association, and ecosystem or environmental changes. Until there are clear recoveries of the affected dolphin stocks, the tuna–dolphin issue is likely to remain highly controversial.

Ursidae

RONALD E. HEINRICH
Ohio University, Athens

The eight species of living bears are characterized by having massive skulls, large (25–780 kg) and heavily built bodies, relatively short and powerful limbs, short tails, a shuffling plantigrade gait, and an omnivorous diet aided by a keen sense of smell and large crushing molar teeth. This uniformity of body plan has a relatively recent evolutionary history, however, with the two earlier ursid radiations, the Amphicynodontinae and Hemicyoninae, exhibiting a greater array of dental and postcranial adaptations than the living bears. Throughout their approximately 37 million year history, ursids have maintained a Holarctic distribution, migrating into Africa on at least four separate occasions and into South America at least once, and were the dominant carnivorans of Eurasia during much of the Oligocene and Miocene. Morphology-based analyses indicate that Ursidae is the sister taxon to Pinnipedia, a phylogenetic hypothesis that has also received some support from molecular studies.

I. Ursid Fossil Record

The earliest recognized ursids, members of the subfamily Amphicynodontinae, first appeared in the late Eocene and early Oligocene fossil records of North America and Eurasia. Before going extinct at the end of the early Miocene, this paraphyletic assemblage of CARNIVORANS gave rise to both the hemicyoninine and ursine ursids and possibly to the basal members of Pinnipedia. Amphicynodonts were generally small to medium sized (< 15 kg), plantigrade or possibly semidigitigrade, and tended to retain a primitive dentition possessing a well-developed pair of carnassial teeth for shearing, triangular rather than quadrate upper molars, and relatively small posterior molar teeth (Fig. 1A). Apomorphic characters shared by these earliest ursids with all later members of the family, however, include a posteriorly wide basioccipital bone, a large broad protocone on the upper carnassial, initial reduction of the parastyle and paraconule on the upper molars (both lost in later ursids), and the presence of a posterior shelf or heel on the lower second molar (Tedford *et al.*, 1994). A more derived amphicynodont was the early Miocene, sea otter-like *Kolponomos*. Collected from coastal deposits along Oregon and Washington. This genus has been reconstructed as semiaquatic with sensitive lips and tactile vibrissae, powerful neck muscles, and broad cheek teeth used to locate, pry off, and then crush, respectively, shelled marine invertebrates found attached to rocky substrates (Tedford *et al.*, 1994). These workers have also argued that among known ursids, *Kolponomos* occupies the position of sister taxon to Pinnipedia.

The second ursid radiation was initiated in the late Oligocene of Eurasia. The Hemicyoninae were the first ursids to attain large body size (upwards of 200 kg) and the only ursids to evolve digitigrady, an adaptation for cursoriality that supports the interpretation of these animals as active PREDATORS comparable in many respects to canids (Hunt, 1998). The dentition of hemicyonines is derived relative to amphicynodonts in that the upper carnassial has a retracted protocone and a shortened metastylar blade, and the upper molars are quadrate due to enlargement and migration of the metaconule (Fig. 1B). Hemicyonines migrated into North America on several occasions and into Africa at least once, but by the latest Miocene they were extinct throughout their geographic range.

The subfamily Ursinae, although primarily a late Miocene and Pliocene radiation, first appeared in the late Oligocene?–early Miocene fossil record of North America. The earliest member of the group, *Ursavus*, was a small to mid-sized Holarctic and plantigrade form that exhibited some of the dental specializations characteristic of later bears, including further reduction (compared to hemicyonines) of the upper carnassial and the development of low-crowned, elongate molars with wrinkled enamel (Hunt, 1998). In modern bears such as *Ursus*, these traits are taken to an extreme with broadening and lengthening of the molar teeth (Fig. 1C), providing an immense grinding surface for processing vegetation. Derived from a species of Eurasian *Ursavus*, *Ursus* first appeared about 5 million years ago (mya) migrating into North America about 4.3 mya and into North Africa about 1 mya. The only bears to have

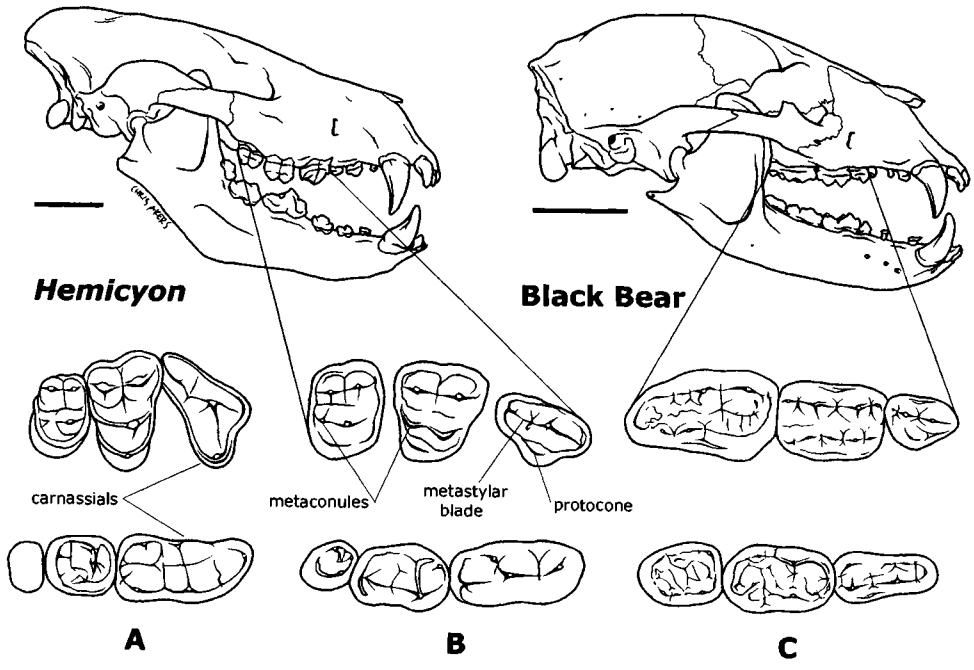

Figure 1 *Comparison of skulls and dentitions of representative members of the three ursid radiations. reached South America belong to the Ursinae and include *Arctodus,* which arrived less than 2 mya, and the living spectacled bear (*Tremarctos*), which has no South American FOSSIL RECORD.

II. Phylogenetic Relationships of Living Ursids

The eight species of living ursid are currently allocated to as few as three (*Ailuropoda, Tremarctos,* and *Ursus*) and as many as five (additionally *Helarctos* and *Melursus*) genera, all of which are monospecific except *Ursus. Tremarctos ornatus* (spectacled bear) and *A. melanoleucus* (giant panda) are successive outgroups to the remaining six species (Fig. 2), and although there has been some contention as to whether the giant panda should be included within the family at all, it is now widely accepted that *Ailuropoda* diverged from other members of Ursinae during the early Miocene. The most recent phylogenetic analysis incorporating both molecular and morphologic data sets (Bininda-Emonds *et al.,* 1999) suggests that the Malayan sun bear (*H. malayanus*) and sloth bear (*M. ursinus*) are sister taxa, that the Asiatic black bear (*U. thibetanus*) is the sister taxon to the clade brown bear (*U. arctos*) + polar bear (*U. maritimus*), and that the position of the American black bear (*U. americanus*) is unresolved with respect to these other two clades (Fig. 2).

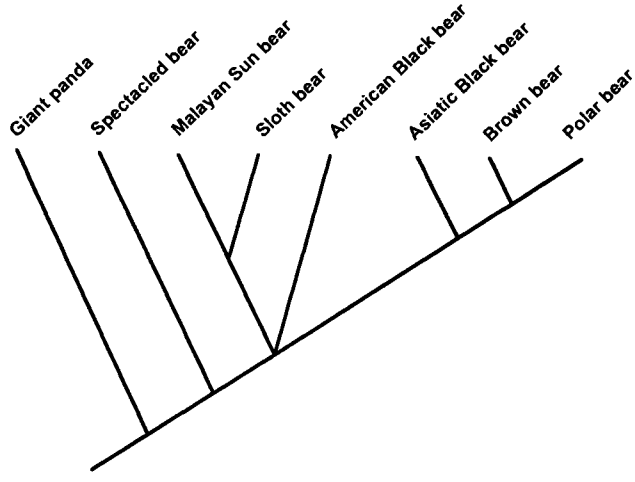

Figure 2 *A cladogram depicting phylogenetic relationships among the eight species of living ursid: the giant panda* (Ailuropoda melanoleucus), *spectacled bear* (Tremarctos ornatus), *Malayan sun bear* (Ursus malayanus), *sloth bear* (U. ursinus), *American black bear* (U. americanus), *Asiatic black bear* (U. thibetanus), *brown bear* (U. arctos), *and polar bear* (U. maritimus). *From Bininda-Emonds* et al. *(1999).*

The only marine-adapted ursine, the polar bear, is thought to have diverged from the brown bear between 100,000 and 250,000 years ago probably as a result of glacial advances that isolated northern and southern populations. Ancestors of the modern polar bear became adapted for life on the sea ice, evolving a denser, hollow fur for protection against the Arctic cold and morphologic characteristics such as sharper claws and carnassial teeth for grasping and shearing through the skin of captured seals. Despite these and other ecological and morphological differences between the two species, polar bears and brown bears are still capable of producing fertile offspring and some biologists have suggested that the Barren Ground grizzly may be such a HYBRID.

V

Vaquita

Phocoena sinus

LORENZO ROJAS-BRACHO AND
ARMANDO JARAMILLO-LEGORRETA
Instituto Nacional de Ecología,
Ensenada, Baja California, Mexico

The vaquita (*Phocoena sinus* Norris and McFarland, 1958), or Gulf of California harbor porpoise, is endemic to the Gulf of California. It is also one of the two most endangered cetacean species in the world (Jefferson *et al.*, 1993). The vaquita is a relatively new species. It was described in 1958 (Norris and McFarland, 1958). However, it was not until the past decades that important advances were made in our knowledge of this highly endangered porpoise.

I. Description, Characters and Taxonomic Relations

The vaquita is the smallest of all the porpoises. The mean length for females is 140.6 cm, whereas males are slightly smaller (134.9 cm). The vaquita differs from other phocoenids not only in total length, but also in that the flippers of the vaquita are proportionately larger and the dorsal fin is taller and more falcate. Generally, the pigmentation pattern is a dark gray cape, pale gray lateral field, and white ventral field. The most conspicuous features of the pigmentation are the relatively large black eye rings and lip patches (Fig. 1). Skulls of adult vaquitas are smaller and have relatively much broader and shorter rostra than those of other members of the genus. The number of tooth pairs in the upper and lower jaw is 16–22 and 17–20, respectively (Brownell *et al.*, 1987; Vidal *et al.*, 1995). Norris and McFarland (1958) suggested that the vaquita diverged from *P. spinipinnis* rather than from *Phocoena phocoena*, its closest geographic phocoenid neighbor. This hypothesis was corroborated almost 37 years later by Rosel *et al.* (1995) using molecular techniques.

II. Abundance, Distribution, and Ecology

The limited ABUNDANCE, distribution, and narrow habitat specificity of vaquita make it one of the rarest marine mammal species. The most recent published population size estimate by Jaramillo-Legorreta *et al.* (1999) was 567 individuals (CV = 0.51, 95% CI 177–1073). All sightings from systematic ship surveys indicate that its DISTRIBUTION is limited to an area north of 30°45'N (Silber *et al.*, 1994; Gerrodette *et al.*, 1995; Vidal, 1995; Jaramillo-Legorreta *et al.*, 1999) specifically to a portion of the upper Gulf of California (see Fig. 2). This is probably the most restricted distribution of any marine cetacean. Vaquita habitat can be described as a region characterized by strong tidal mixing, convection processes, high turbidity, high nutrient concentration, and primary and secondary productivity. In this environment, most vaquita sightings have been in waters 11–50 m deep, 11 to 25 km from the coast, and over silt and clay bottoms (Silber *et al.*, 1994; Gallo and Torre, 1998). It is known that vaquitas move to the eastern coast of the upper Gulf, mainly from recovered specimens (beached and bycaught) and not so much from sightings (Vidal *et al.*, 1999).

Analysis of stomach contents of 34 vaquitas reveals them to be nonselective feeders (Findley *et al.*, 1995; Pérez-Cortés, 1996). Prey consisted primarily of a wide variety of demersal/benthic fishes (21 species), squid (2 species), and crustaceans (1 species, plus 2 that were fish parasites). Several of the fish prey species (such as croakers, Scianidae) are known to be sound producers so it is possible that vaquitas are frequently using passive sound rather than echolocation to find their prey.

III. Life History and Behavior

The only published paper on the life history of the vaquita is that by Hohn *et al.* (1996). Arguably the most striking aspect of this work is the unusual age distribution of the vaquita. Most individuals (62%) were found to be between 0 and 2 years of age. The remainder of individuals (31%) were between 11 and 16 years of age, with few specimens determined to be between 3 and 10 years. There was a complete absence of individuals between the ages of 3 and 6 years.

The sample of animals may be biased due to spatial segregation of different age classes or the susceptibility of various ages to be captured in nets. Alternatively, if this were the true

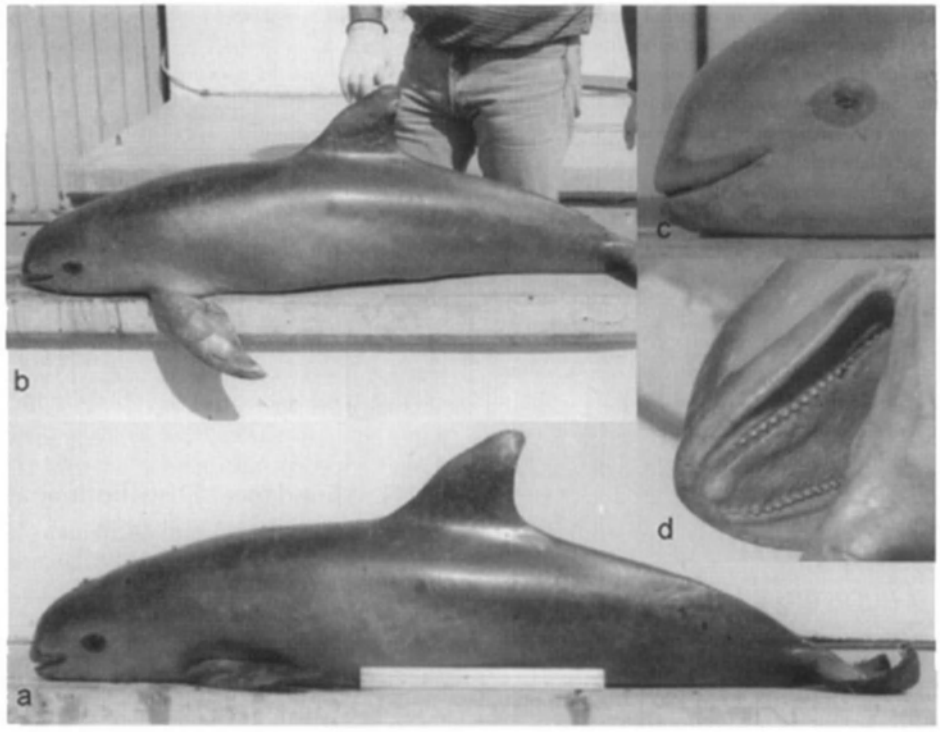

Figure 1 *Morphology of the vaquita. (a and b) Lateral views. Note proportionally large dorsal and pectoral fins. (c) Lateral view of the head showing the dark patches surrounding the eye and lips. (d) Ventral view of the mouth showing the palate and the spade-shaped crown of teeth (courtesy of Armando Jaramillo-Legorreta).*

age distribution of the population, this would represent a complete recruitment failure in recent years.

Like other porpoises, the vaquita is a seasonal reproducer, with most births occurring around March. There are no data, but gestation is probably 10–11 months, as with other porpoises. The maximum observed life span is 21 years, which is consistent with the maximum life span of the harbor porpoise, *Phocoena phocoena*. Age of sexual maturity is difficult to estimate because of the lack of juvenile animals in the sample, but all females less than 3 years were immature and all females older than 6 years were mature. Most female harbor porpoises mature at age 3 and give birth first at age 4, which is consistent with these observations for the vaquita. Reproductive rates could not be estimated accurately, but unlike harbor porpoises in the Gulf of Maine, vaquitas are probably not annual reproducers.

No pathological study of the recovered specimens has been published. However, morphological abnormalities in the vertebrae, unusual number of digits (six), and pathological condition of the ovaries (calcification of corpora albicantia) have been reported (Ortega-Ortiz *et al.*, 1993; Torre-Cosío, 1995; Hohn *et al.*, 1996).

Little is known of the social organization of the vaquita. Mean school size is two, but groups as large as 8 or 10 individuals have been reported. An important aspect is the loose aggregating behavior. The dynamics of these group aggregations are not clear. However, it seems that either their duration is short or they shift locations in short periods of time. For example, Jaramillo-Legorreta *et al.* (1999) reported 41 vaquita groups loosely aggregated over several hundred square meters. During the next days and couple of weeks later, this group aggregation was not found. There are also indications that suggest that shrimp trawlers are related to this aggregating behavior (Jaramillo-Legorreta *et al.*, 1999).

The vaquita, like other phocoenids, has the capacity to produce narrow band high-frequency clicks (Silber, 1991). The primary use of this sound must be ECHOLOCATION, although its role in COMMUNICATION could be important in the turbid and dynamic environment of the Upper Gulf of California. Evidence indicates that the clicking rate is lower for the vaquita than for the harbor porpoise. The shallow waters inhabited by the vaquita can be a reason for this, as vaquitas can be looking for prey visually at the bottom for longer periods. Further acoustical studies can reveal areas with differential ecological uses by the vaquita.

IV. Conservation Status

The vaquita is classified in the most critical conservation categories by the International Union for the Conservation of Nature (IUCN, 1996), Convention on International Trade in the Endangered Species of Wild Fauna and Flora (1997), and the Mexican government (Norma Oficial Mexicana, DOF 16 de Mayo, 1994). In 1996, the IUCN concluded that the extinction of the vaquita is likely unless CONSERVATION EFFORTS are increased substantially.

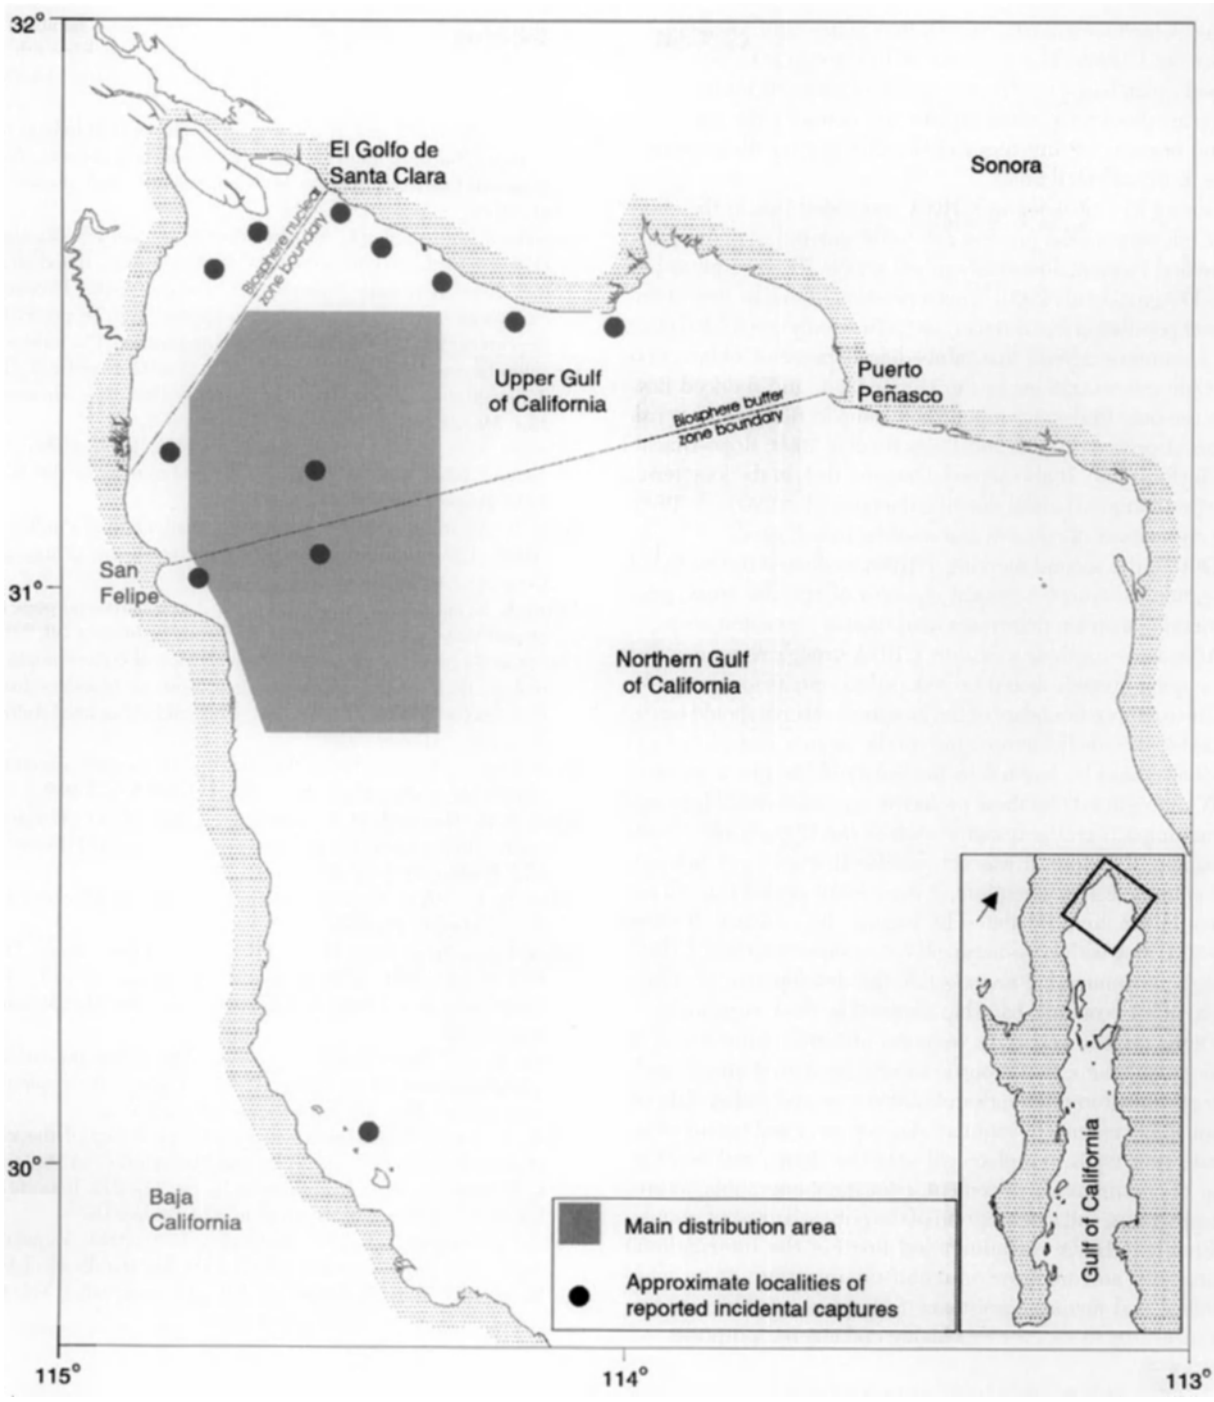

Figure 2 *The Upper Gulf of California. The core area of distribution (gray) was sketched from sightings data. Solid circles represent localities where bycaught vaquitas have been reported.*

To protect the vaquita and other endangered species, the Mexican government created the Upper Gulf of California and Colorado River Delta Biosphere Reserve on June 10, 1993. However, as new knowledge of the vaquita has been gained, it is clear that this measure is insufficient. Results of the surveys in 1993 and 1997 indicate that the boundaries of this biosphere reserve do not correspond well to the distribution of vaquitas. A large percentage of the sightings (40%) lie outside the reserve boundary (Fig. 2). Further, no sightings were within the nuclear zone of the reserve, which is the area where all fishing is prohibited (Gerrodette *et al.*, 1995; Jaramillo-Legorreta *et al.*, 1999).

A more specific action has been the creation of the International Committee for the Recovery of the Vaquita (CIRVA) by the Mexican government. Recognized scientists from the

United Kingdom, Canada, the United States, and Mexico participate in CIRVA. The mandate of this group is to propose a recovery plan based on the best available scientific information. The plan should also contemplate and consider the socioeconomic impacts of any required regulations on the resource users in the affected areas.

During its first meeting, CIRVA concluded that in the short term, gill nets are the greatest risk to the survival of the vaquita. Estimated incidental mortality in gill nets is 39–84 vaquitas per year (D'Agrosa *et al.*, 2000). This represents from 6 to 14% of the current population size estimate and is from only one fishing port. The committee agreed that inbreeding depression, chlorinated pesticide concentrations in the Upper Gulf, and reduced flow from the only freshwater input (the Colorado River) are not risk factors at present (Taylor and Rojas-Bracho, 1999; Rojas-Bracho and Taylor, 1999). It also agreed, however, that, in the long term, changes in vaquita habitat due to reduction of the Colorado River flow are matters of concern and must be investigated.

During the second meeting, CIRVA evaluated the potential mitigation measures: seasonal closures of specific areas, gear restriction, acoustic deterrents, and marine-protected areas.

After analyzing these measures, CIRVA strongly recommended that vaquita bycatch should be reduced to zero as soon as possible, the southern boundary of the biosphere reserve should be expanded to include the entire range of the vaquita, and gill net and trawlers should be banned in the enlarged biosphere reserve. CIRVA recognized that these protective measures would have significant impacts on the resource users of the Upper Gulf of California and, therefore, it was not possible to implement full protection immediately. Therefore, it was recommended that gill net fishing in the areas inhabited by vaquitas be removed in three stages, starting with large-mesh gill nets. Considering this, CIRVA strongly recommended investigating the development of strategies to offset economic hardship imposed by these regulations.

Other recommendations were the effective enforcement of fishing regulations; that acoustic surveys be started immediately to begin monitoring an index of abundance and gather data on seasonal movements of vaquitas; development and testing of alternate gear types to replace gill nets; the design and development of community involvement, education, and public awareness programs; and a description of the critical habitat of vaquita.

Finally, CIRVA recommended inviting the international community and nongovernmental organizations to provide technical and financial assistance to implement the conservation measures to recover this highly endangered porpoise.

Vision

ALLA M. MASS AND ALEXANDER YA. SUPIN
Russian Academy of Sciences, Moscow

The vision of marine mammals has a number of specific features associated with its ability to function in both water and air. Although many marine mammals (cetaceans, sirenians) spend their entire life in water, their aer-

ial breathing confines them to a near-surface layer of water. Other marine mammals (pinnipeds, sea otters) spend a significant part of their life on land. As a result, the organization of their visual system fits requirements of both these different media. Although some aspects of organization of the visual system of marine mammals still remain unstudied, many features of their vision are known already.

I. Visual Abilities of Marine Mammals

A. Cetaceans

It was long believed that dolphins—animals with excellent hearing and echolocation—have a poorly developed visual system playing a minor role in their life. However, observations of the visual activity of dolphins have demonstrated the opposite. The ability to catch fish in air, to perform precisely aimed jumps to reach targets above the water, and to recognize their trainers all show that vision in dolphins is well developed. In conditions of captivity, dolphins decrease their use of echolocation and, as their interest in events above the water increases, vision takes on a leading role.

Reviews of Madsen and Herman (1980) and Mobley and Helweg (1990) summarize observations of dolphins in CAPTIVITY and experimental studies that provide a basis for regarding the vision of dolphins as playing an important role in various aspects of their life: in social interactions, in discrimination between individuals and species based on their colors and individual marks, in the search and discrimination of prey, in orientation, in reproductive activity, and in defense. Only vision provides the ability for rapid and precise assessment of distances to objects in air where echolocation does not operate.

Apart from numerous observations, good visual abilities of cetaceans were demonstrated in behavioral experiments for assessing their visual acuity. Precise behavioral measurements performed by Herman and colleagues (see Madsen and Herman, 1980) on the bottlenose dolphin (*Tursiops truncatus*) resulted in an estimate of underwater visual acuity of 8.2 arc min (at the best distance of 1 m) and aerial visual acuity of 12.5 arc min (at distances of 2.5 m and longer). In general, estimates of visual acuity in dolphins varied from 8 to 27 arc min in water and from 12 to 18 arc min in air.

Studies of color vision in cetaceans are very few in number. Only one cone type was found in the bottlenose dolphin, with the best sensitivity at 525 nm; rods are best sensitive to 488 nm. These sensitivity peaks are considerably blue-shifted as compared to those of many terrestrial mammals (Jacobs, 1993). Therefore, the dolphin lacks the common dichromatic vision typical of many terrestrial mammals, which is based on two cone types with different chromatic sensitivity. If color vision is present in dolphins (basing on comparison of signals from rods and cones), it is poorly developed and limited to a blue–green region of the spectrum.

In all cetaceans, the eyes are positioned laterally, thus providing a visual field as wide as 120–130° and panoramic vision. Although positioned laterally, the eyes are directed somewhat forward and downward (ventronasally). On viewing visual objects in air, the dolphin eyes can move forward by 10–15 mm so that the visual fields of the two eyes overlap by 20–30° in the frontal sector, giving a basis for binocular vision. However, uncrossed optic fibers have not yet been demonstrated in dolphins. Therefore, the existence of true binocular (stereoscopis) vision (based on interaction of crossed and uncrossed optic fibers) in dolphins still remains under question.

Dolphins are equally capable of the perception of complex configurations of objects using both vision and echolocation. Besides, there is also a possibility of intermodal transfer between these two modalities: objects known for a dolphin only by visual appearance can be discriminated and recognized by echolocation, and vice versa. The intermodal transfer is equally successful when visual experience is used for echolocation discrimination and when echolocation experience is used for visual discrimination.

Even in riverine cetaceans inhabiting turbid and low-transparent water (the Amazon river dolphin, *Inia geoffrensis*, the tucuxi, *Sotalia fluviatilis*), the visual system does not exhibit a significant regression. The only exception is the Indian river dolphin, *Platanista gangetica*, in which the visual system is reduced markedly.

B. Pinnipeds

Because pinnipeds spend their life partially in water and partially on land, they use both underwater and aerial vision. On land, vision plays an important role during the reproductive period, during birth and feeding of pups, and for maintaining intrapopulation relationships, as well as for orientation. In water, vision is used for prey detection and recognition, for avoiding predators, and for spatial orientation during MIGRATIONS.

Because of a great diversity of pinniped species in terms of systematic position and ecology, the role of vision diverges widely as well. Walruses (*Odobenus rosmarus*) rely mainly on their vibrissal sensitivity to identify objects during benthic foraging. Other pinnipeds also have a well-developed vibrissal apparatus; however, in aquatic conditions, most seals use both visual and tactile modalities to search for food. Experiments demonstrated that seals are able to distinguish rather small objects visually, to recognize the shape of figures, and to perform a complex analysis of visual images. Data summarized by Fobes and Smock (1981) showed that both otariids and phocids are capable of discriminating objects differing in size from 9 to 24%.

Most pinnipeds (both otariids and phocids) have maximum spectral sensitivity within a range of 496–500 nm. An exception is the southern elephant seal (*Mirounga leonina*), which is sensitive to a shorter wavelength (486 nm).

A possibility of limited color discrimination in a few pinniped species (*Pagophilus groenlandicus, Phoca larga, Arctocephalus pusillus, A. australis*) is indicated by their capability to discriminate blue and green objects from gray ones, although they cannot discriminate red and gray objects. The best rod sensitivity in the harbor seal (*Phoca vitulina*) was found at 496 nm and cone sensitivity at 510 nm; i.e., similar to dolphins, the spectral sensitivity is blue-shifted as compared to terrestrial mammals. No indication was obtained of more than one cone type in pinnipeds.

Measurements of visual acuity based on the use of grids as test stimuli have demonstrated that visual acuity in both water and air is 5–8 arc min in a few otariid species: *Zalophus californianus, Eumetopias jubatus, Arctocephalus pusillus*, and *A. australis*.

C. Other Marine Mammals

1. Sirenians There has been no detailed investigation of visual capabilities in sirenians. A few observations summarized by Piggins *et al.* (1983) showed that the Amazon manatee (*Trichechus inunguis*) is capable of visually driven behavior, particularly visual tracking of underwater objects. A capability of the Caribbean manatee, *Trichechus manatus*, for dichromatic (blue–green) color vision has been shown. It remains unknown whether the manatee has an ability of good aerial vision.

2. Sea Otters Very little is known of the visual abilities of sea otters (*Enhydra lutris*). Inhabiting the coastal zone and feeding underwater, sea otters need to have good vision in both air and water. Observations showed that they actively use vision, and experiments have shown their capability to discriminate objects of different sizes. However, quantitative behavioral measurements of their visual abilities are absent.

II. Eye Anatomy and Optics

A. Cetaceans

Ocular anatomy in cetaceans is markedly different from that in terrestrial mammals by being adjusted to optical properties of water and to a number of other factors: possibility of eye damage because of high density of water and presence of suspended particles, low temperature and low illumination deep in water, significant light scatter, and so on. Characteristic examples of eye structure in cetaceans are shown in Fig. 1. Remarkable features are a thick sclera (especially so in whales, Fig. 1B), a thickened cornea, a highly developed vascular network forming a typical vascular rete mirabilia, which fills a significant part of the orbit behind the eyeball, and massive ocular muscles. All of these structures take part in protecting the eye from underwater cooling and mechanical damage.

While in terrestrial mammals the eyeball is almost spherical, in cetaceans its anterior part is flattened so that the anterior chamber is small and the eyecup is of almost a hemispherical shape. More precisely, the eyecup shape approximates a segment of a sphere of about 150° of arc (Figs. 1A and 1B), and its nasotemporal diameter slightly exceeds the dorsoventral one.

In terrestrial mammals, the convex outer surface of the cornea is the major refractive element of the eye because it separates media with different refractive indices: air with a refractive index of about 1 and the corneal tissue with a refractive index of more than 1.35. However, the refractive index of water is 1.33–1.34, which is very close to that of the cornea and the intraocular media. As a result, the corneal surface plays very little part in underwater light refraction. Therefore, in cetaceans, light refraction and focusing of an image on the retina are almost entirely performed by the lens. This is why

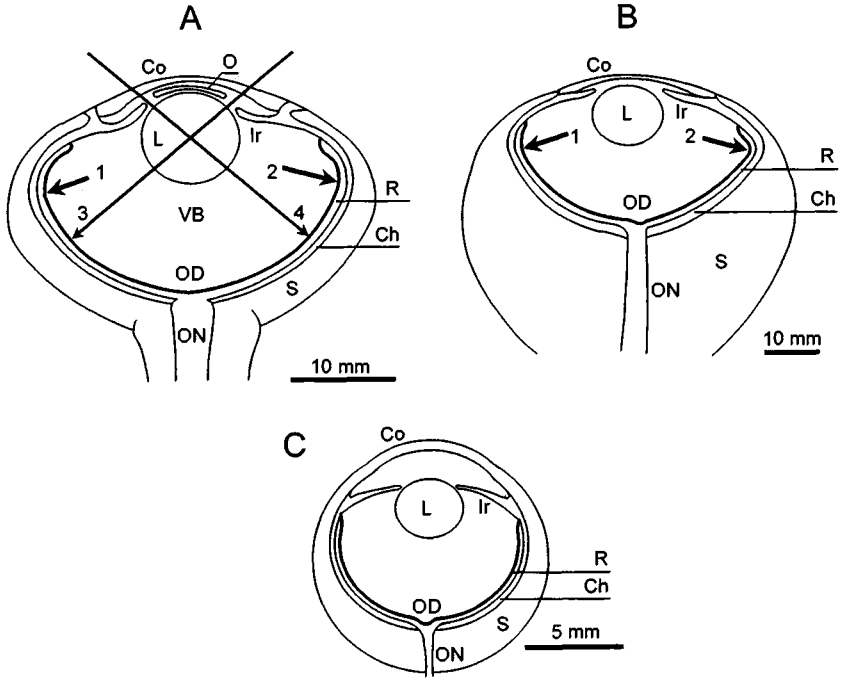

Figure 1 *Schematic presentation of eye anatomy and optics in some cetaceans: (A) the common bottlenose dolphin, (B) the gray whale* (Eschrichtius robustus), *and (C) the Amazon river dolphin. Co, cornea; L, lens; Ir, iris; O, operculum; S, sclera; Ch, choroid; R, retina; ON, optic nerve; OD, optic disc; VB, vitreous body. Arrows 1 and 2 delimit a part of the eyecup, which can be approximated by a spherical segment of about 150°. Arrows 3 and 4 show directions of light rays passing through the nasal and temporal holes of the pupil and through the lens center to the high-resolution parts of the retina.*

the lens in cetaceans is almost spherical or slightly elliptical. The large curvature of the lens surface provides a sufficiently high refractive power of the lens and well-focused images on the retina, despite very weak refractive power of the corneal surface in water. These optics are similar to those in fish, which is not surprising given that in both cases the eye is adjusted to optical properties of the same medium.

A strongly convex (spherical) lens consisting of homogeneous material has a very strong spherical aberration. The cetacean lens is free of this disadvantage due to a heterogeneous structure: outer layers have a lower refractive index than the inner core.

In the cetacean eye, the spherical lens is located in such a way that its center almost coincides with the center of the spherical segment of the eyecup, so light rays coming from any direction are focused almost identically on the retina. This is significantly different from the case in terrestrial mammals, which provides the best focusing on the eye axis.

In terrestrial mammal eyes, accommodation (refraction adjustment to the distance to the object) is performed by a change in the shape of the lens due to contraction and relaxation of ciliary muscles. In cetaceans, spherical lens shape and center-symmetric optics of the eye led to loss of this accommodatory mechanism. The ciliary muscles are poorly developed in dolphins and are absent in most whales, suggesting that accommodation cannot be achieved by changing the lens shape. It has been suggested that accommodation in cetaceans is performed by another mechanism, namely by axial displacement of the lens due to changes in intraocular pressure. Intraocular pressure can change because of contraction of the retractor/protractor muscles, which produce axial displacements of the eye in the orbit. When the eye is pulled back into the orbit, intraocular pressure increases, thus shifting the lens forward; when the eye is moved forward, the pressure decreases, shifting the lens backward.

The cornea in cetaceans is thicker than in many terrestrial mammals, and this thickness is not uniform: the cornea is thinner in the center and thicker in the periphery. Although major refraction in the cetacean eye is performed by the lens, the refractive role of the cornea is not negligible. Its outer surface is of lower curvature than the inner one; i.e., the cornea has a shape of a divergent lens. Under water, this lens makes a minor contribution to the total refraction power, as the media on both sides of the cornea (water outside and the anterior chamber liquid inside) have refractive indices rather close to that of the cornea. However, some difference between the refractive indices of water (1.33) and the cornea (from 1.37 in the central part to 1.53 in the periphery) does exist. Thus, the cornea acts a weak but nonetheless divergent lens. The total refraction of the cornea and lens makes the cetacean eye well emmetropic within a range of ± 1 diopters under water.

Adaptation to underwater vision also affects the cetacean iris and pupil. Cetacean vision functions in conditions of wide and rapid changes of illumination when the animal dives from the well-illuminated water surface into the depths where illumination is very low. This requires the pupil to react in a wide range of illuminations and to have a wide range of sizes. The cetacean pupil is of an unusual shape. The upper part of the iris has a characteristic protuberance, the operculum. At low illumination, the operculum is contracted (raised), so the pupil, similarly to other mammals, is of a round or slightly oval shape; its horizontal diameter in dolphins is of about 10 mm (Fig. 2A). With illumination increased, the operculum advances downward, turning the pupil into a U-shaped slit (Fig. 2B). At high illumination, the operculum advances so far that the slit becomes closed, leaving only two narrow holes in the temporal and nasal parts of the iris (Fig. 2C). This pupil shape is characteristic for many dolphins, including the bottlenose dolphin, harbor porpoise (*Phocoena phocoena*), common dolphins (*Delphinus* spp.), tucuxi, and also for a number of whales, although in some whales the operculum is small. A known exception is the Amazon river dolphin, which has a round pupil even when it is constricted.

The cetacean eye is well emmetropic in water; however, in air refraction on the outer convex corneal surface adds to the lens refraction. The difference of refractive indices of air and the cornea results in significant refractive power of the central most convex part of the corneal surface: about 20 diopters. The addition of this refraction to the emmetropic lens refraction should make the cetacean eye catastrophically myopic (near-seeing) in air. Nonetheless, dolphins have good visual acuity in both water and air.

The solution of the problem is in the presence of flattened (low-curvature) regions of the cornea. A flat corneal surface does not produced additional refraction in air. Even if the surface is not truly flat but a little convex, its refractive power becomes low enough and may be compensated by some additional mechanisms. Keratoscopis studies in common bottlenose dolphins showed a "spoon" shape of the cornea with lower curvature in its nasal and temporal regions.

Aerial myopia can be partially compensated by accommodatory displacements of the lens. For aerial vision, the dolphin eye moves forward, thus producing a decrease of intraocular pressure; this results in shifting the lens backward and reduced myopia. Additionally, reduction of intraocular pressure decreases the curvature of the cornea. Under water, the eye is retracted into the orbit, which results in increased intraocular pressure and a shift of the lens forward to a position providing underwater emmetropia.

An additional mechanism for the correction of aerial myopia is pupil constriction. Above water, high illumination results in

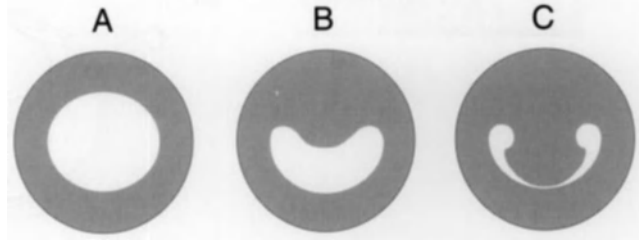

Figure 2 *Shape of the pupil in the common bottlenose dolphin at various levels of illumination: (A) low illumination, nonconstricted oval pupil; (B) moderate illumination, partially constricted U-shaped pupil; and (C) high illumination, strongly constricted pupil reduced to two pinholes.*

strong pupil constriction; the latter corrects all errors of refraction, including aerial myopia, and provides a fairly good depth of field.

Another adaptation of the cetacean eye to low underwater illumination is the well-developed reflective layer, the tapetum lucidum. It lies behind the retinal pigment epithelium within the choroid. In cetaceans, the tapetum is formed with extracellular collagen fibrils (*tapetum fibrosum*). Multiple reflection of light from 50 to 70 layers of fibrils results in significant light reflection back to the retina, thus increasing visual sensitivity in scotopic conditions.

The tapetum is present in all cetaceans. In most investigated cetaceans, particularly in mysticete whales, it covers all of the fundus (although it varies in coloration), or at least it covers a large dorsal part of the fundus. Complete coverage of the fundus by the tapetum is unique among vertebrates: in terrestrial mammals, the tapetum usually does not extend lower than the horizontal equator of the eyecup.

B. Pinnipeds

In all pinnipeds (except walruses), both the absolute and the relative sizes of the eyeball are large. The eye structure in pinnipeds (Fig. 3A), despite significant differences from cetaceans, has some common features arising from adaptation to underwater vision (Jamieson and Fisher, 1972). In particular, a characteristic feature is an almost spherical or slightly elliptical lens. Although the eyeball does not appear as shortened in the axial direction, a major part of the eyecup has a shape close to a hemisphere so a significant part of the retina is almost constantly distant from the lens center. Thus, the eye optics, like in cetaceans, is almost centrally symmetrical. The difference between the eyeball shape in cetaceans and pinnipeds (shorter axial length in cetaceans and longer in pinnipeds) is mainly due to the larger size of the anterior chamber in pinnipeds.

The iris in pinnipeds is very muscular and heavily vascularized. The dilator is well developed. All pinnipeds have a pupil, which being constricted becomes pear-shaped, except for a diagonal pupil in the bearded seal, *Erignathus barbatus*. Pupil size can change over a very wide range; at bright illumination, it constricts to a very small hole. The ciliary muscle in pinnipeds is well developed, although accommodation is either absent or very weak.

Unlike cetaceans, the central part of the cornea has a clearly delimited region (6–10 mm in diameter) of almost a flat surface. It is located near the center of the cornea, slightly shifted to the nasal direction (FC region in Fig. 3A). Such a flat region of the cornea was found in a number of both otariids and phocids and was demonstrated by precise measurements on the Californian sea lion (*Zalophus californianus*). The flat region of the cornea serves as an emmetropic "window" in which refraction remains almost equal in both water and air. In another pinniped, the hooded seal (*Cystophora cristata*), the flattened part of the cornea does not look like a delimited region but arises because of low curvature of the cornea of the extremely large eyeball.

The existence of a flat region in the central part of the cornea indicates a very specific principle of eye construction in pin-

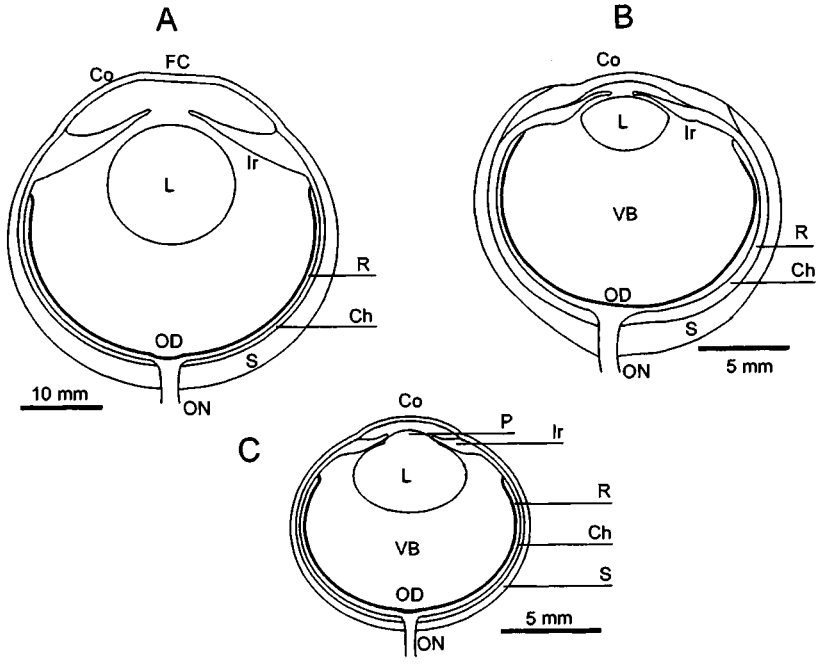

Figure 3 *Schematic presentation of eye anatomy and optics in some representatives of pinnipeds, sirenians, and otters: (A) the northern fur seal, (B) the manatee, and (C) the sea otter. Co, cornea; FC, flattened region of the cornea; L, lens; Ir, Iris; S, sclera; Ch, choroid; R, retina; ON, optic nerve; OD, optic disc; P, lens protuberance; VB, vitreous body.*

nipeds. Indeed, the convex shape of the cornea in most animals is a consequence of excessive intraocular pressure, which is necessary for maintaining the shape and size of the eyeball. Direct data on intraocular pressure in pinnipeds are absent, but their flat cornea suggests that this pressure is very low, perhaps about zero. Anatomical observations on the northern fur seal (*Callorhinus ursinus*) showed that its vitreous body is of a rigid rather than a gelatinous consistency, thus taking a part in maintenance of the eyeball shape and dimensions. This way of maintaining the eye shape is evidently used in a number of pinniped species.

The pinniped tapetum is one of the best developed among both terrestrial and aquatic mammals. Contrary to the tapetum fibrosum in cetacean, the tapetum in pinnipeds is formed with intracellular reflective rodlets (tapetum cellulosum). It consists of a large number (20–30 or more) of cell layers and covers all of the fundus.

C. Other Marine Mammals

1. Sirenians Among other marine mammals, the eye anatomy of the manatees (*Trichechus manatus* and *T. inunguis*) is of interest as an example of the order Sirenia, which, apart of cetaceans, is the only group of completely aquatic mammals.

Both in *T. manatus* and *T. inunguis* the eye is rather small (13–19 mm diameter) and is set deeply within the ocular fascia. Its general morphology resembles more that of terrestrial mammals than the cetacean eye (Fig. 3B). The eyeball is almost spherical (the axial length differs little from the equatorial diameter), the anterior chamber is shallow, and the lens is set forward and is not truly spherical: its axial dimension is markedly shorter than the diameter. The sclera is rather thin. Thus, despite the completely aquatic mode of life of the manatee, its eye anatomy exhibits a number of conservative features (Piggins *et al.*, 1983). Underwater, the eye is almost emmetropic or slightly hyperopic, but in air it is strongly myopic. It remains unknown whether the manatee has some mechanism to compensate aerial myopia; thus, its capability to aerial vision remain unknown.

2. Sea Otters To a large extent, the eyeball of the sea otter (*Enhydra lutris*) is similar to those of terrestrial mammals (Fig. 3C): it is almost spherical, the axial length is only a little shorter than the diameter. Contrary to spherical lenses of cetaceans and pinnipeds, the lens of the sea otter is lenticular. However, the front surface of the lens has a protuberance of increased curvature. A characteristic feature of the eye anatomy is that the iris is fastened to the frontal lens surface. Therefore, contraction of iris muscles influences the curvature of the frontal lens surface. This mechanism is capable of providing an accommodation range of up to 60 diopters, thus compensating for the appearance of refraction at the corneal surface in air and its disappearance in water. This accommodation mechanism in the sea otter eye is able to preserve emmetropia in both air and water.

III. Eye Movements

All dolphins and whales have mobile eyes. However, measurements in the bottlenose dolphin indicate that eye mobility is less than in humans, and eye movements are slower.

Oculomotor muscles are well developed in dolphins and whales; an exception is the Indian river dolphin (*Platanista gangetica*), which has reduced eyes and no oculomotor muscles. Other cetaceans have a complete set of muscles known in mammals: four straight and two oblique muscles. These muscles allow eye movements in both the horizontal and the vertical directions. In addition, unlike terrestrial mammals, cetaceans have retractor/protractor muscles (m. retractor bulbi and m. protractor bulbi), which produce axial (in/out) movements of the eye in the orbit. The bottlenose dolphin is capable of moving its eye forward 10–15 mm and pulling it back. As a rule, forward eye movements (protraction) appear when the dolphin examines an object in air visually. These eye movements may be used for the binocular examination of objects. As mentioned earlier, the eye protraction in air can also provide accommodation to avoid aerial myopia.

Another intriguing factor of oculomotor activity in dolphins is the ability to move the left and right eyes independently. Quantitative measurements in dolphins have shown that the correlation of movements of the left and right eyes is very low; i.e., independent eye movements in dolphins are a rule rather than exception.

In addition to independent eye movements, cetaceans have rather independent pupil reflexes of the two eyes. Moreover, eyelids of the left and right eyes can also function independently so one eye can be open while the other is closed. Such observations were made during sleep in dolphins, although similar behavior is also possible in wakefulness: dolphins can swim for long periods with one eye open and the other one closed, with the left and right eye alternating.

As to pinnipeds and sea otters, there is no significant difference from terrestrial mammals in their oculomotor muscle anatomy and the character of eye movements.

IV. The Retina and Optic Nerve

A. Features of the Retina in Cetaceans

The histological structure of the retina has been investigated in a number of cetacean species: the common bottlenose dolphin, short-beaked common dolphin (*Delphinus delphis*), Dall's porpoise (*Phocoenoides dalli*), dwarf sperm whale (*Kogia sima*), Amazon river dolphin, fin whale (*Balaenoptera physalus*), and common minke whale (*B. acutorostrata*). All of these studies have shown that the laminal structure of the cetacean retina is basically similar to that in terrestrial mammals. The retina consists of typical layers as follows (Fig. 4). The receptor layer (the nearest to the pigment epithelium) is composed of densely packed outer segments of photoreceptors. The outer nuclear layer is composed of receptor pericaria arranged in a multilevel manner. The outer plexiform layer contains cell processes establishing connections between receptors and first-order neurons, bipolar cells. The inner nuclear layer is composed mostly of pericaria of bipolar cells; in addition, this layer contains horizontal and amacrine cells, which establish horizontal connections within the outer and the inner plexiform layers. The inner plexiform layer contains processes establishing connections between bipolar and ganglion cells. The ganglion layer contains ganglion cells sending their axons to the optic nerve. Finally, the nerve fiber

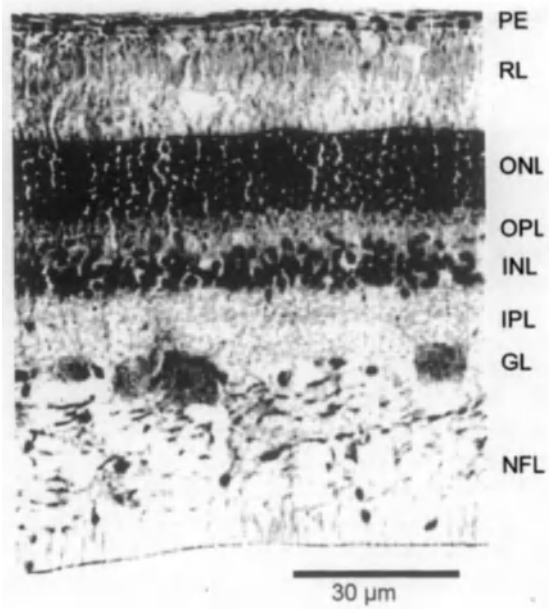

Figure 4 *Microphotographs of a transverse section of the retina of a Dall's porpoise. PE, pigment epithelium; RL, receptor layer; ONL, outer nuclear layer; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GL, ganglion layer; NFL, nerve fiber layer. layer (nearest to the vitreous body) contains optic fibers (axons of ganglion cells), which spread along the inner/retinal surface until they reach the optic disk and enter the optic nerve. This laminar structure of the retina is fully developed in all cetaceans. Even in the Indian river dolphin with strongly reduced eyes, the retina contains all the layers. Being basically similar in cetaceans and terrestrial mammals, the retina has a number of specific features in cetaceans. It is markedly thicker than in terrestrial mammals, ranging from 370 to 425 μm (in terrestrial mammals, the retina is 110–240 μm thick).

The most detailed description of the retina is available for the common bottlenose dolphin (Dral, 1977; Dawson, 1980). Its retinal receptor layer consists predominantly of rods (receptors for achromatic vision). The question of the existence of cones (chromatic-vision receptors) in cetaceans is still debatable; if cones exist, they are few in number. This corresponds to behavioral data showing poor color vision in dolphins (see Section I,A). As to amacrine, bipolar, and horizontal cells in the cetacean retina, they are generally similar to those in terrestrial mammals.

A marked difference from terrestrial mammals is in the inner plexiform layer and the ganglion layer of the cetacean retina. The ganglion layer looks like a single row of large, sparsely distributed neurons separated by large intercellular spaces. These neurons have large cell bodies with a clearly defined cell membrane, a large amount of cytoplasm, a well-visible nucleus up to 15 μm in diameter, and a clearly defined nucleolus 4–5 μm in diameter. Cell bodies contain clearly visible, well-stained Nissl granules.

A remarkable feature of the cetacean retina is the large size of ganglion cells, particularly the presence of giant ganglion cells. Bodies of such cells reach 75–80 μm, sometimes more. Giant ganglion cells were described in a number of odontocete species and in a few mysticete whales. In some dolphins, however, retinal ganglion cells do not reach giant sizes: in the Amazon river dolphin and the Indian river dolphin they do not exceed 40–42 and 20 μm, respectively. However, even these cells are large as compared to those in many other mammals. The smallest ganglion cells in cetaceans are as large as 10 μm.

Figures 5A and 5B present ganglion cell size distributions in the retina of the common bottlenose dolphin. The histograms represent samples in different parts of the retina: with high and low concentration of ganglion cells. Despite some difference between the samples (in the area of high cell concentration, cells are a little smaller than in the area of low concentration), both samples demonstrate large cell sizes: the most common size is 20–35 μm, but cells as large as 50–60 μm are also present; there are no cells smaller than 10 μm.

Large cells are not characteristic of all levels of the visual system in cetaceans (the lateral geniculate body, visual cortex); they are typical only in the retina. The largest pyramidal cells in the visual area of the dolphin cerebral cortex are not more than 20–30 μm. In other parts of the dolphin brain, cells do not exceed 20–45 μm either. There is presently no satisfactory explanation why ganglion cells in the cetacean retina are so large. One possible explanation is that large ganglion cells have thick axons with a high velocity of conduction; in a large body, it may be helpful for the fast transmission of signals. However, large terrestrial mammals (e.g., the bull or elephant) have ganglion cells no larger than 25–30 μm.

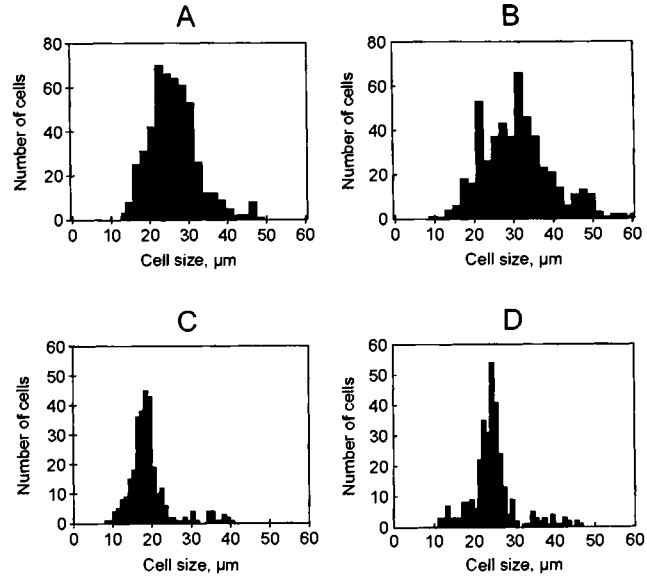

Figure 5 *Histograms showing size distributions of ganglion cells in the retina of cetaceans and pinnipeds. Abscissa axis, cell size; ordinate axis, number of cells of the present size. (A and B) Data from a common bottlenose dolphin; samples from areas of high (A) and low (B) cell densities. (C and D) The same for a northern fur seal.*

Apart from large cell sizes, a characteristic feature of the retinal ganglion layer in cetaceans is low cell density. The large neurons are separated by large intercellular spaces.

The question of separation of retinal ganglion cells into different morphological types has not been solved for cetaceans. Large-size ganglion cells in cetaceans resemble large Y neurons in the visual system of terrestrial mammals, as opposed to smaller X neurons. However, Y neurons in terrestrial mammals constitute no more than 1% of ganglion cells, whereas in cetaceans, large ganglion cells predominate.

B. Optic Nerve Structure in Cetaceans

Retinal ganglion cells send their axons into the optic nerve. Consistent with the large sizes of ganglion cell bodies, the axon diameters in cetaceans are also greater than in terrestrial mammals. In a variety of dolphin species, a significant proportion of optic fibers exceed 15 μm in diameter. For comparison, the maximum fiber diameter in cats and monkeys is no more than 8 μm. The only exception is the Chinese river dolphin, *Lipotes vexillifer*, which has thin optic fibers, although its retina contains ganglion cells as large as 75 μm.

The low density of ganglion cells in the retina of cetaceans corresponds to the low density of fibers in the optic nerve. In cross sections of the optic nerve of dolphins, the density of fibers is less than 50,000/mm^2, whereas in monkeys it exceeds 220,000/mm^2. Thus, although the optic nerve in cetaceans is of a larger diameter, the total number of optic fibers does not exceed that in many terrestrial mammals. More than 50% of the cross section area of the cetacean optic nerve is occupied by intercellular space (as opposed to 12–20% in terrestrial mammals), not by glia.

The total number of optic fibers varies among cetacean species. The smallest number of fibers (14,000–16,000) was found in the Indian river dolphin, *Platanista gangetica*, and the Amazon river dolphin, *Inia geoffrensis*; the number of optic fibers in the Chinese river dolphin, *Lipotes vexillifer*, is a little higher, more than 20,000. In the common bottlenose dolphin, the number of optic fibers is 150,000–180,000. Other odontocetes have an optic fiber number similar to that in the bottlenose dolphin. In mysticetes, the number of optic fibers is within a range of 250,000–420,000.

C. Features of the Retina in Pinnipeds

In general, the retinal structure in pinnipeds is the same as in terrestrial mammals. All layers are present in the pinniped retina, although there are a number of specific features, mainly of the inner nuclear and ganglion layers (Jamison and Fisher, 1972).

The inner nuclear layer in pinnipeds does not have clear margins, in contrast to terrestrial mammals, where this layer is strictly ordered. There are large horizontal cells with very long processes within this layer. The giant horizontal cells are located irregularly among bipolar and amacrine cells, which are also distributed chaotically. Bipolar cells are located mostly in the outer part of the inner nuclear layer while large amacrine cells are located close to the inner plexiform layer.

The ganglion layer in pinnipeds consists of a single row of ganglion cells separated by wide intercellular distances. Ganglion cells have large pericaria, a large amount of Nissl substance in the cytoplasm and long dendrites. Most of these cells are of intermediate size (10–30 μm), although large cells (up to 50 μm) are also encountered (Figs. 5C and 5D). These sizes are smaller than in cetaceans, although larger than in terrestrial mammals.

All pinnipeds have a predominately rod retina. However, light and electron microscopy has shown the presence of cones in the harbor seal and harp seal, although photoreceptors of this type are not numerous. The existence of some amount of cones corresponds to behavioral data showing a limited capability of color discrimination in pinnipeds (see Section I,B).

D. The Retina of Other Marine Mammals

1. Sirenians The retina of the manatees also features the common laminar organization. Receptors are presented mostly by rods; cones are less numerous. Among specific features, the large size of the ganglion cells can be mentioned: up to 60 μm, mostly 15–30 μm, and not less than 10 μm. Thus, the large size of ganglion cells seems to be a common feature of different groups of marine mammals.

2. Sea Otters In the sea otter, the retina has many features similar to those in terrestrial rather than in aquatic mammals. The majority of ganglion cells are not of large size: 7 to 30 μm, mostly 11–15 μm. They can be subdivided into three size groups: large, medium, and small. The retina of the sea otter contains a large number of small amarcine and neuroglial cells.

V. Retinal Topography and Visual Field Organization

A. Cetaceans

Ganglion cells are distributed nonuniformly in the mammalian retina: ganglion cell density (number of cells per area unit) is high in some areas and much lower in the remainder of the retina. Regions of ganglion cell concentration (high density) provide the most detailed analysis of visual images. Characteristics of retinal topography in a variety of mammals are presented in a review by Hughes (1977).

In terrestrial mammals, there are two main types of organization of a region with high cell density. In mammals with frontal vision, highest density is in the fovea or area centralis located in the center of the visual field. This retinal area is little vascularized to avoid its shadowing by blood vessels. In mammals with laterally located eyes, the region of high cell density is shaped as a narrow horizontal strip, the visual streak. All terrestrial mammals studies up until now have only one, if any, region of highest ganglion cell density.

The cetacean retina does not have avascular areas, indicating the presence of fovea or area centralis. Therefore, visual examination of the eye fundus is not capable of revealing such regions. Data on the topography of ganglion cell distribution in the cetacean retina were obtained using retinal whole mounts. Whole mounts are preparation of a total retina flattened on a slide, ganglion layer upward, and stained appropriately. Retinal whole mounts allow one to count ganglion cells systematically across all of the retina surface, thus constructing a topographic map of ganglion cell distribution. Studies of retinal whole mounts have shown that different regions of the cetacean retina have a very

different density of ganglion cells (Fig. 6). Beginning from the pioneering studies of Dral (1977), studies of cetacean retinal whole mounts were performed in a number of dolphin species, particularly the common dolphin, common bottlenose dolphin, harbor porpoise, Dall's porpoise, and Pacific white-sided dolphin (*Lagenorhynchus obliquidens*) (see review by Mass, 1997).

The most characteristic feature of these species is that, unlike terrestrial mammals, all of these marine dolphins do not have a single area of high ganglion cell density but two such areas. They are located near the horizontal diameter of the retina, one in the nasal and the other in the temporal sector (Fig. 7A). In the bottlenose dolphin, both of these areas are located at a distance of 15–16 mm from the optic disk, which corresponds to 50–55° of the visual field. Ganglion cell density in each of these areas reaches 700–800 cells/mm^2, which corresponds to 40–50 cells per squared degree of the visual field (cells/deg^2). The two high-density areas are connected by an elongated zone of increased, although somewhat lower, cell density, which runs below the optic disk; this zone looks like a visual streak.

In other dolphin species, the retinal topography is basically similar to that described earlier: there are two areas of high ganglion cell density. Even at low cell density in some cetaceans inhabiting turbid and low-transparent water (e.g., the tucuxi), the retinal topography looks the same (Fig. 7B). However, some quantitative differences do exist. In the bottlenose dolphin, the ganglion cell density is almost equal in the two areas, the nasal and the temporal areas, whereas in the harbor porpoise, the cell density in the temporal area (i.e., the region serving the frontal visual field) is higher than in the nasal region: 28 and 20 cells/deg^2, respectively.

The retinal topography of ganglion cells was studied in two mysticete species: the gray whale, *Eschrichtius robustus*, and common minke whale (*Balaenoptera acutorostrata*). Both of them also have ganglion cell distributions with two area of high cell density in the nasal and temporal sectors (Fig. 7C). Again, the cell density in the temporal area is higher than in the nasal one: 28 and 21 cells/deg^2 in the gray whale.

The significance of the two areas of high ganglion cell density (i.e., of high retinal resolution) is probably associated with the cetacean's capability of good vision both above and under water, in particular, with preventing aerial miopia. Indeed, the high-resolution areas are located just opposite the two small pupil holes formed when the pupil is constricted in air (see Fig. 1A). Because of the centrally symmetric optics of the cetacean eye, light falls onto each of these areas through the opposite hole of the pupil. The areas of the cornea with minimal curvature are located across from these narrow pupil holes. Both the pinhole pupils and the low cornea curvature are devices to prevent aerial miopia. Thus, images are projected onto the high-resolution areas of the retina with minimal distortions.

The two high-resolution retinal areas in cetaceans may be used differently for underwater and aerial vision (see Mass, 1997). When a dolphin looks at an underwater object, it takes a position lateral to the object; i.e., the object is placed into the posterolateral part of the visual field, which projects onto the nasal high-resolution area of the retina. On the contrary, when a dolphin looks at an object above water, it places the object into the ventronasal part of the visual field, which projects onto the temporal high-resolution area of the retina (Fig. 8). Of course, the temporal high-resolution area of the retina also participates in underwater vision. This area serves the frontal part of the visual field, which is very important for forward-moving animals. The existence of two high-resolution areas of the retina can also compensate for the limited head mobility in many cetaceans. At low head mobility, even at high mobility of the eyes, a single high-resolution area allows the animal to inspect only a limited part of the surrounding space, whereas two such areas can provide almost panoramic vision.

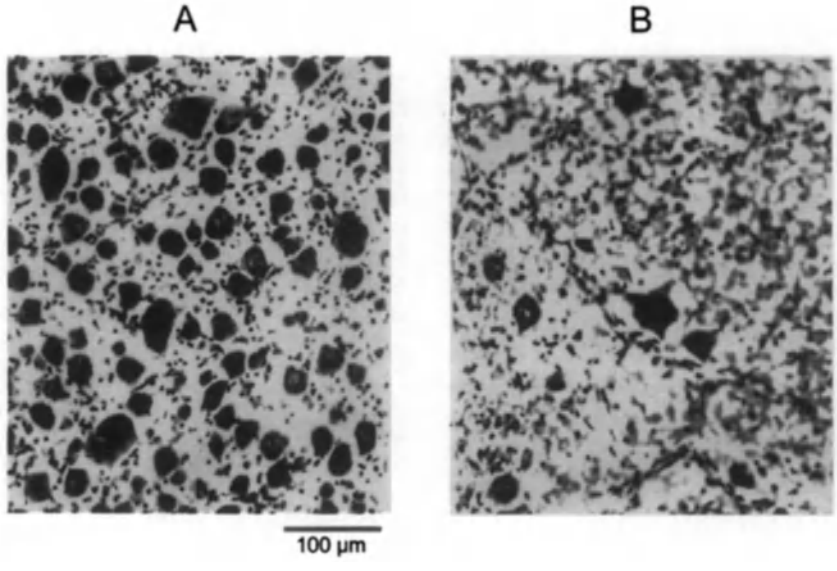

Figure 6 *Microphotographs of the ganglion layer in a retinal whole mount of a bottlenose dolphin: (A) an area of high cell density and (B) an area of low cell density.*

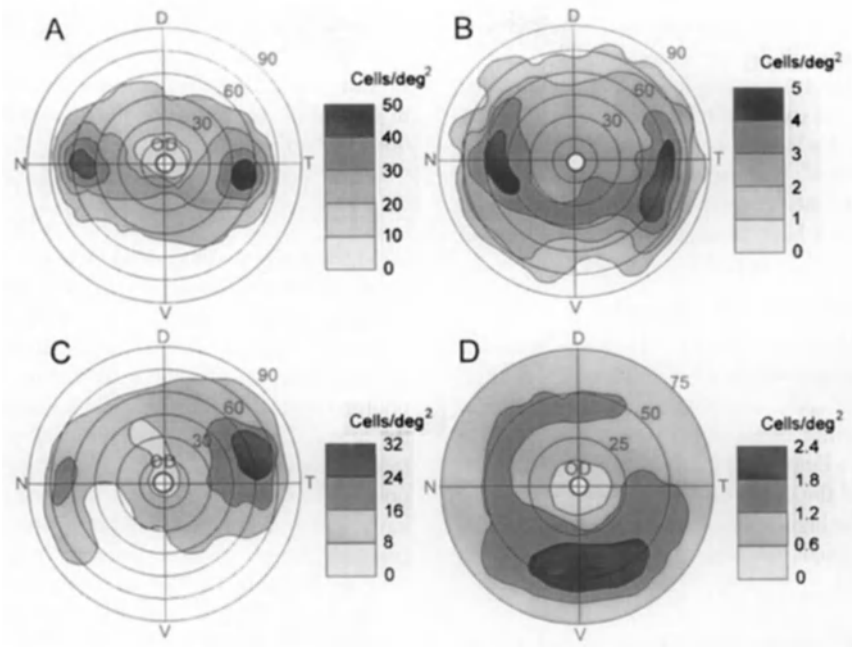

Figure 7 *Topographic distribution of ganglion cell density in the retina of some cetaceans: (A) the common bottlenose dolphin, (B) the tucuxi dolphin, (C) the gray whale, and (D) the Amazon river dolphin. Cell density is expressed as number of cells per squared degree of the visual field and is shown by various shadowing, according to the scales. Concentric circles show angular coordinates on a retinal hemisphere centered on the lens. D, V, N, T, dorsal, ventral, nasal, and temporal poles of the retina, respectively.*

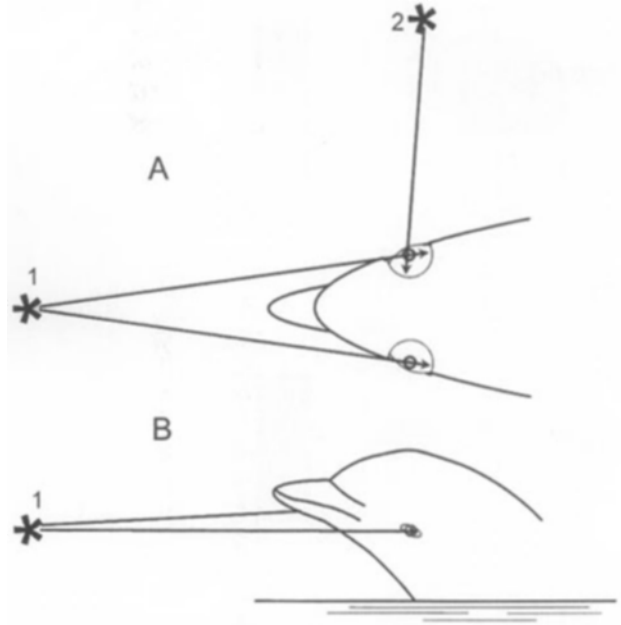

Figure 8 *Characteristic positions of the dolphin body relative to visually inspected objects: (A) Dorsal view (for both underwater and aerial vision) and (B) lateral view (for aerial vision). 1, an above water object: 2, an underwater object. Arrows show directions of light rays from an object to the corresponding high-resolution area of the retina.*

The retina of the Amazon river dolphin is a special case. The visual system of this species is adapted to low-transparent turbid water where vision is possible only at short distances. Contrary to all other investigated cetaceans, the retina of the Amazon river dolphin has only one area of higher ganglion cell density. However, this single area is located not in the center or temporal sector, but in the lower part of the retina, i.e., in the region responsible for the upper part of the visual field (Fig. 7D). In turbid low-transparent water, significant illumination exists only near the water surface, i.e., in the upper part of the visual field of a normally oriented aninal. Just this part of the visual field is served by the ventral part of the retina where the Amazon dolphin has higher retinal resolution. The density of ganglion cells in this region reaches 500 cells/mm^2; with the small size of the eyeball, this corresponds to a cell density of about 2 cells/deg^2.

B. Pinnipeds

Few otariids have been subjects of study of the ganglion cell topography in retinal whole mounts (Mass, 1997). The northern fur seal has a typical area centralis, a well-defined area of high concentration of ganglion cells (Fig. 9A). It is located at a distance of 22–23 mm (which corresponds to 35–40° of the visual field) from the optic disk; taking into account the position of the eye in orbit, this place may be at the projection of the vertical meridian of the visual field. Thus, the position of this area is similar to that in terrestrial carnivores. Cell density in this area reaches 1000 cells/mm^2, which corresponds to more than 160 cells/deg^2.

Quite different is the retinal topography in the walrus. The area of increased ganglion cell density is not defined as clearly as in the northern fur seal. It looks like a horizontally extended oval, resembling the visual streak of terrestrial mammals (Fig. 9B). Within this streak, the highest cell density in its temporal part exceeds 1000 cells/mm^2; because of the smaller size of the walrus eye, this cell density corresponds to only about 50 cells/deg^2. No phocid seals have been studied successfully yet with respect to their retinal topography.

C. Other Marine Mammals

1. Sirenians Ganglion cell distribution in the manatee retina represents an example of low specialization. There is no sharply restricted spot of cell concentration. Ganglion cell distribution is not uniform but varies smoothly across the retina: cell density is higher in a large center part of the retina (except in the nearest vicinity of the optic disk) and diminishes toward the edges (Fig. 9C). The highest cell density is about 250–300 cells/mm^2; for a rather small manatee eye, this corresponds to 6–7 cells/deg^2.

2. Sea Otters In the sea otter retina ganglion cells topography (Fig. 9D) has a number of features similar to that of terrestrial mammals. The high-density area resembles nasotemporal streak. Within this streak, in its temporal part, there is a narrow and well-defined spot of the highest cell density, which is similar to the area centralis in terrestrial mammals. The highest ganglion cell density in the sea otter exceeds 4000 cells/mm^2; in the rather small eye of the sea otter, this corresponds to 50–60 cells/deg^2.

D. Estimations of Visual Acuity from Ganglion Cell Density

Visual acuity is determined by two factors: quality of the eye optics and retinal resolution. In normal eyes, these two values are in agreement. Therefore, retinal resolution can be used as a first-order estimate of visual acuity. Retinal resolution depends on the density of ganglion cells (not of other retinal cells, e.g., photoreceptors, as ganglion cells transmit visual information to the brain). Thus, data on ganglion cell topography can be used to estimate the visual acuity of investigated species. When it is possible to compare estimates of visual acuity obtained by behavioral (psychophysical) methods and those based on ganglion cell topography, these estimates are in good agreement.

Retinal resolution (hence, visual acuity) is defined as the mean angular distance between neighboring ganglion cells, i.e., as $s = 1/\sqrt{D}$, where s is the angular distance between cells and D is the cell density per deg^2. The estimation of retinal resolution is different in air and water: if the corneal surface is flat, the retinal image of an object in water is 1.33 times larger than

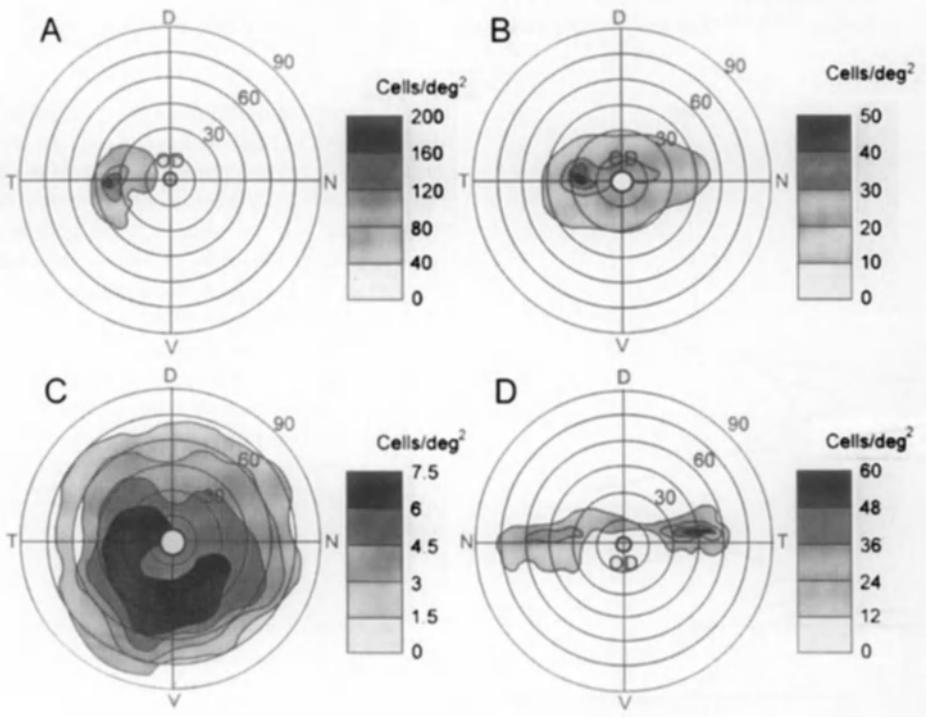

Figure 9 *Topographic distribution of ganglion cell density in the retina of some pinnipeds, sirenians, and sea otters: (A) the northern fur seal, (B) the walrus, (C) the Caribbean manatee, and (D) the sea otter. Cell density is expressed as number of cells per squared degree of the visual field and is shown by various shadowing, according to the scales. Concentric circles show angular coordinates on a retinal hemisphere centered on the lens. D, V, N, T, dorsal, ventral, nasal, and temporal poles of the retina, respectively.*

in air (because the ratio of refraction indices of water and air is 1.33). Therefore, retinal resolution in water is 1.33 times better than in air. If the retinal surface is a little convex, this factor is less than 1.33 but still more than 1.

Retinal resolution in the areas of the highest concentration of ganglion cells (i.e., visual acuity in the best-vision areas of the visual field) was estimated in a number of marine mammal species (Table I). In many cetaceans (except for river dolphins), it varies from 8 to 12 arc min in water, correspondingly from 11 to 15 arc min in air. For the bottlenose dolphin, the estimation of visual acuity obtained from retinal topography almost coincides with that obtained in behavioral experiments. In general the visual acuity of cetaceans is within a range of visual acuities of many terrestrial mammals, except the foveal vision of primates, where the visual acuity is around 1 arc min. The Amazon river dolphin has much worse visual acuity: 40–50 arc min in water; however, this value is adequate for vision in turbid water where objects are visible at best at a few tens of centimeters.

Among pinnipeds, rather acute vision is characteristic for the northern fur seal: better than 5 arc min in water and better than 7 arc min in air. This is close to estimates obtained in behavioral experiments in a number of both otariids and phocids: 5–8 arc min (Schusterman, 1972). In the walrus, the visual acuity is worse than in seals: around 8 arc min in water and 10 arc min in air.

In the manatee, underwater visual acuity is around 20 arc min (it remains unknown whether the manatee has good aerial vision). In the sea otter, the visual acuity is around 7 arc min in water.

VI. Cerebral Visual Centers

In dolphins, the visual system is well represented in the midbrain (the superior colliculus), thalamus (the lateral geniculate

TABLE I
Visual Acuity of Some Aquatic Mammals[a]

Species	*Water*	*Air*	*Mode of measurement*
Odontoceti			
Common bottlenose dolphin (*Tursiops truncatus*)	8–9	11–12	BR
Short-beaked common dolphin (*Delphinus delphis*)	8		R
Harbor porpoise (*Phocoena phocoena*)	11	15	R
Tucuxi dolphin (*Sotalia fluviatilis*)	25	33	R

Sea otter (*Enhydra lutris*)	7		R

[a]Visual acuity is presented as the minimal resolvable distance in minutes of arc, rounded to a whole number of minutes. In some cases, a range of variation is indicated (e.g., 11–12 arc min). Estimates of visual acuity are given for underwater (*water*) and aerial (*air*) vision. In the column *air*, data are not presented when none of the authors attempted to interpret their results in terms of aerial visual acuity. When several estimates of visual acuity in different conditions are available (e.g., in the nasal and temporal best-vision areas in cetaceans, at various illumination conditions, etc.), the best estimate (i.e., the minimal resolvable distance) is selected. Mode of measurement: B, behavioral data; R, data on retinal resolution.

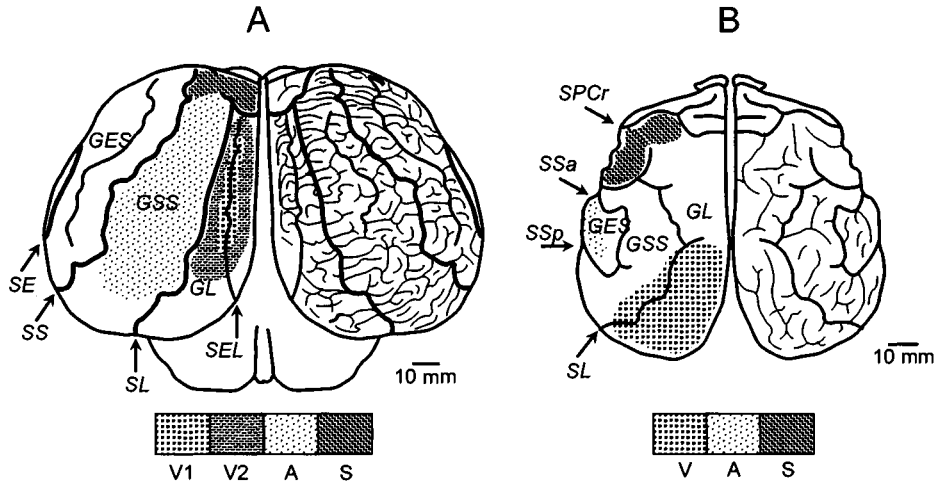

Figure 10 *Position of projection sensory areas (visual, auditory, and somatosensory) in the cerebral cortex of cetaceans and pinnipeds: (A) the common bottlenose dolphin and (B) the northern fur seal. Dorsal view of the cerebral cortex. On the right hemisphere, the pattern of cortical sulci and gyri is shown in more detail. On the left hemisphere, only main cortical sulci are shown and the positions of the visual, auditory, and somatosensory areas are indicated. The main sulci (labeled by arrows at their ends): SE, sulcus ectosylvius; SS, s. suprasylvius; SL, s. lateralis; SEL, s. entolateralis; Ssa, s. suprasylvius anterior; Ssp, s. suprasylvius posterior; SPCr, s. postcruciatus. The main gyri (labeled on their surface): GES, gyrus ectosylvius; GSS, g. suprasylvius; GL, g. lateralis; V, visual area (V1, primary projection zone; V2, nonprimary zone); A, auditory area (only a part of this area is visible in B); S, somatosensory area.*

body), and in the cerebral cortex. However, the visual centers (both the superior colliculus and the lateral geniculate body) are several times less in volume than corresponding parts of the auditory system (the inferior colliculus and medial geniculate body).

In the cerebral cortex of dolphins, visual representation was found by the evoked potential method. This area occupies a part of the cortex named the lateral gyrus (Fig. 10A). The cortical representation of the visual system in dolphins also is not as large as that of the auditory system; nevertheless, it occupies a significant cortical area. There is a differentiation within this area: it contains a zone generating short latency-evoked potentials (i.e., the primary projection zone) and another zone generating evoked potentials of longer latency (a nonprimary zone). The first of them is located in the depth of the entolateral sulcus (a second-order sulcus within the lateral gyrus); the latter occupies the remainder of the lateral gyrus. These two zones differ in cytoarchitectonic features: the primary projection zone contains an incipient layer IV (the layer where visual thalamocortical afferent fibers end), whereas this layer is absent in the nonprimary zone.

In mysticetes, which do not have echolocation, the sizes of visual and auditory structures in the midbrain and thalamus are comparable. Their cortical sensory areas were not investigated.

Among pinnipeds, visual representation in the cerebral cortex was found by the evoked potential method in one otariid species—the northern fur seal (Fig. 10B)—and one phocid species—the Caspian seal, *Pusa caspica*. The location of this area is very similar to that in carnivores: the projection occupies the caudal part of the lateral gyrus.

VII. Conclusions

In general, the visual system of marine mammals demonstrates a rather high degree of development and performance, in particular, good visual acuity, capabilities to precisely aim visually driven BEHAVIOR and intermodal transfer, and well-developed visual brain centers. This system also exhibits a number of specific features associated with adaptation to both aquatic and aerial environment, in particular, specific retinal topography (positions of best-vision areas) along with pupil and cornea structure, which provide emmetropia in both air and water.

Walrus

Odobenus rosmarus

Ronald A. Kastelein
Harderwijk Marine Mammal Park, The Netherlands

The walrus is the single species of the pinniped family Odobenidae, distinguished by the upper canines in both sexes being prolonged as tusks. Walruses feed mainly on small organisms on the ocean floor, while almost all other pinnipeds feed primarily on highly mobile fish and crustaceans. For an animal of such a large size, this predator consumes organisms that are relatively low in the food chain. The DIET of the walrus influences its biology: compared to other pinnipeds, the walrus has a less streamlined body, swims more slowly, and dives less deeply. Its sensory systems are adapted to its bentic foraging technique.

I. Classification

The Latin name *Odobenus rosmarus* means "tooth walking sea horse." The genus *Odobenus* consists of only one species: *O. rosmarus*. Two subspecies are recognized based on morphological characteristics and on mitochondrial DNA divergence: Pacific walrus, *Odobenus rosmarus divergens* (Illiger, 1815) and Atlantic walrus, *O. rosmarus rosmarus* (Linnaeus, 1758). A potential third subspecies, the Laptev walrus, *O. rosmarus laptevi* (Chapski, 1940), is dubiously distinct from *O. rosmarus divergens*.

II. External Characteristics

The walrus is the largest pinniped except for the male elephant seal (*Mirounga* spp). The body is rotund; the girth at axilla is almost equal to body length. Males are larger than females of the same age. Adult Pacific walruses are on average slightly larger than adult Atlantic walruses of the same gender. Adult male walruses have an average body length of around 320 cm and weight 1200–1500 kg, whereas adult females have a body length of around 270 cm and weigh 600–850 kg. Regional differences in body size per gender and age class exist.

Walruses are easily distinguished from other pinnipeds by their flat noses and enlarged upper canines that form huge tusks. Males have longer and thicker tusks than females. The tusks grow throughout life but growth is usually balanced by tooth wear. The larger whiskers on the upper lips are translucent and yellowish and are directed forward. The eyes are small relative to body size compared to other pinniped species. They are positioned high on the head and can be protruded and retracted. There are no external pinnae. The color of the skin varies from a (lighter) gray when the walrus has just left cold water (Fig. 1) to a (darker) yellowish brown when it is warm and dry (Fig. 2). The fur is very short and in some areas of the body is absent. Although much variation exists, walruses generally molt inconspicuously between May and June and grow new pelage in July and August. The appendages are hairless and the palms and soles are rough. The skin is 2–4 cm thick and very tough. It is thickest around the neck (about 4 cm) and in the area above the whiskers, which is used for plowing through the ocean floor. The skin on the neck of adult males is thicker than that of females and is covered with fibrous tubercles (Fig. 2).

Figure 1 *An adult male Pacific walrus just arriving nearshore from a long foraging journey at sea. Note the light gray color of the skin, which is due to a reduced blood flow to the skin during low temperatures. Photo by Steve Rice, U.S. Fish and Wildlife Service.*

Figure 2 *An adult male Pacific walrus. Note the large diameter of its tusks, the bulging eye, which is turned to look backward, and the pronounced tubercles of the skin on the neck. The latter feature is only seen in adult males. Photo by Steve Rice, U.S. Fish and Wildlife Service.*

Figure 4 *A side view of a Pacific walrus skull showing the open dorsal side of the orbital cavity and the slit in the zygomatic arch, which in life is filled with cartilage. Photo by Ron Kastelein.*

These tubercles are 1 cm thicker than the surrounding skin, protect the underlying tissues against tusk attacks by other males, and are an important visual sexual characteristic. The blubber layer thickness varies depending on the part of the body and season and can be up to 10 cm.

III. Anatomy

A. Skeleton

The skull has some distinct features that relate to the ecology of the walrus. It is very thick and strong as an adaptation to breaking through ice to make breathing holes. The front of the skull of an adult walrus is much higher and broader than that of other pinnipeds to accommodate the large tusks (Figs. 3 and 4). Males, which have thicker tusks than females, also have broader skulls. The tusks are composed of dentine covered with a thin layer of cementum. The ivory of walruses can be distinguished from that of other mammals by its central globular dentine. The heavy weight of the lower jaw probably serves to increase the impact of the tusks. The walrus is able to use its tusks to haul its body upward onto land or ice because of the strong neck muscles attached to the large mastoid processes and the strong hinge between these processes: the condyle of the occipital bone. The zygomatic arch below the orbital cavity contains a strip of cartilage, probably to dampen shocks from the tusks to the braincase. In contrast to most pinnipeds, the orbital cavity is not closed on the dorsal side of the head, allowing the walrus to look upward during plowing through the substrate.

Figure 3 *A ventral view of a Pacific walrus skull showing the large mastoid processes on the sides and well-developed occipital condyle (the hinge to the neck vertebra), the arched roof of the mouth, and the heavy lower jaw. Photo by Ron Kastelein.*

The spinal column consists of 7 cervical, 14 thoracic (occasionally 15), 6 lumbar (occasionally 5), 4 sacral, and 8 or 9 caudal vertebrae. There are 14–15 pairs of ribs.

The hind flippers of the walrus rotate forward like those of otariids, for LOCOMOTION on ice and land. The females have a 1- to 2-cm-long clitoris bone. The penis bone (BACULUM) of adult males is up to 62 cm long.

B. Muscles

Many of the muscles in the upper lip of the walrus are used to erect the whiskers in unison, although whiskers can be moved individually, as well.

The tongue muscles are very strong and are used to create a low pressure in the mouth to extract the soft parts from clams. The mastication muscles are not very large, as the walrus usually does not chew its prey but swallows it whole. The cheek muscles are strong so that the walrus can produce powerful water jets from its mouth to wash sediment away from its prey.

The muscles in the hind limbs are similar to those in otariids. The adult walrus is so heavy and rotund that it does not lift its belly off the substrate when it moves on land or ice. Only calves can walk with only their flippers touching the substrate. In the water the hind flippers are used for propulsion and the front flippers mainly for steering.

C. Respiratory System

The trachea is supported by cartilaginous rings throughout its length. It passes between the lungs for a third of their length before bifurcating into bronchi. The lateral walls of the pharynx of subadult and adult males are extremely elastic and, when inflated, form air sacs (pharyncheal pouches). These sacs are used as resonance chambers for the production of the bell-like sounds underwater and also for floatation when resting in the water.

D. Digestive System

The mouth is narrow and bordered by the tusks. The roof of the mouth is very concave, allowing room for the large tongue that acts as a piston when retracted quickly. The force (of up to −119 kPa) generated by this piston is used to extract the soft parts of clams from their shells. Nontusk teeth are worn down to the gums in wild animals, perhaps by sand moving in the mouth during FEEDING. Teeth are pointed in captive walruses that are fed fish. The dental formula of the Pacific walrus' permanent dentition is as follows:

	(1)-(2)-3	1	1-2-3-(4)	(1)-(2)
Incisors ----- Canines -- Premolar ----- Molar ---- ×2 = 18 to 38 teeth				
	(1)-(2)-(3)	1	2-3-4	(1)-(2)

Teeth in parentheses are present in less than 50% of the adult specimens.

The tip of the tongue may be rounded or bifid. The stomach consists of one J-shaped cavity. The intestines are 10–15 times the length of the animal.

E. Cardiovascular System

A conspicuous aortic bulb is present at the base of the aortic arch. The arteries to the fore limbs are larger than those to the hind limbs. This is related to the division of the muscle masses for the limbs; the muscles of the neck and shoulders are more developed than those of the pelvis area.

F. Reproductive System

The testes are situated between the skin and the muscles. The penis is normally retracted into an opening posterior to the umbilicus. The uterus is bicornate and each horn opens separately into the vagina. Walruses usually have four nipples.

IV. Habitat

The walrus is found in the Arctic, where its DISTRIBUTION is limited by the availability of shallow water foraging grounds and thickness of ice. Walruses prefer relatively shallow water over continental shelves because they feed on invertebrates, which occur on the ocean floor up to a depth of about 80 m. Walruses can break through ice up to about 20 cm thick, but when the ice is thicker than this, they retreat to areas with drift ice. Thus, in winter, walruses inhabit those regions of the drifting ice where leads and polynyas (open water) are numerous and where the ice is thick enough to support their weight.

Male Pacific walruses rest in traditional terrestrial haul-out sites (sand, cobble, or boulder beaches), whereas females and calves prefer to haul out on pack ice or ice floes. In summer, males rest and molt while hauled out on land close to their feeding grounds (Fig. 5). Females molt when hauled out on ice. Atlantic walruses also molt in the summer; during that time, both males and females (sometimes in the same groups) haul out on both land and ice.

V. Distribution, Migration, Abundance, and Conservation Status

The Pacific walrus is found principally in the Bering Sea south to Bristol Bay and Kamchatka and in the Chukchi Sea, although in summer it may enter the Beaufort Sea and East Siberian Sea (Fig. 6). Breeding occurs in late winter in the marginal ice zone of the Bering Sea. The location of the main breeding sites varies depending on the state of the ice, but is generally southwest of Nunivak Island and southwest of St. Lawrence Island. Pacific walruses move north in spring with the receding and drifting ice; females give birth on ice floes, which drift north. They move south in autumn, following the movement of the pack ice. Their swimming speed is approximately 10 km/hr. For most of the year, sexes and age classes live separately. The population is estimated at around 200,000 animals.

The Atlantic walrus is found in the western and eastern Atlantic Arctic (Fig. 6). Within their range, Atlantic walruses occur in several (perhaps eight) more or less well-defined subpopulations: five to the west and three to the east of Greenland. In the western Atlantic Arctic, walruses range from the East Canadian Arctic to West Greenland, including Davis Strait, Baffin Bay, the archipelago in the Canadian high Arctic, and Foxe Basin. The western Atlantic population is estimated at >10,000. In the eastern Atlantic Arctic, walruses range from eastern Greenland to Svalbard (Norway), Franz Josef Land (Russia), and the Barents and Kara Seas. The eastern Atlantic population is estimated to be in the low thousands. Movement studies have shown a connection between walruses at Franz Josef Land and Svalbard and between the latter area and eastern Greenland.

The Laptev walrus (if this population is recognized as a subspecies) is found only in the Laptev Sea (Fig. 6). The population has been estimated at 4000–5000 animals.

Figure 5 *A large group of male Pacific walruses hauled out on Round Island, Bristol Bay, Alaska. Note how closely the animals are packed together. Photo by Steve Rice, U.S. Fish and Wildlife Service.*

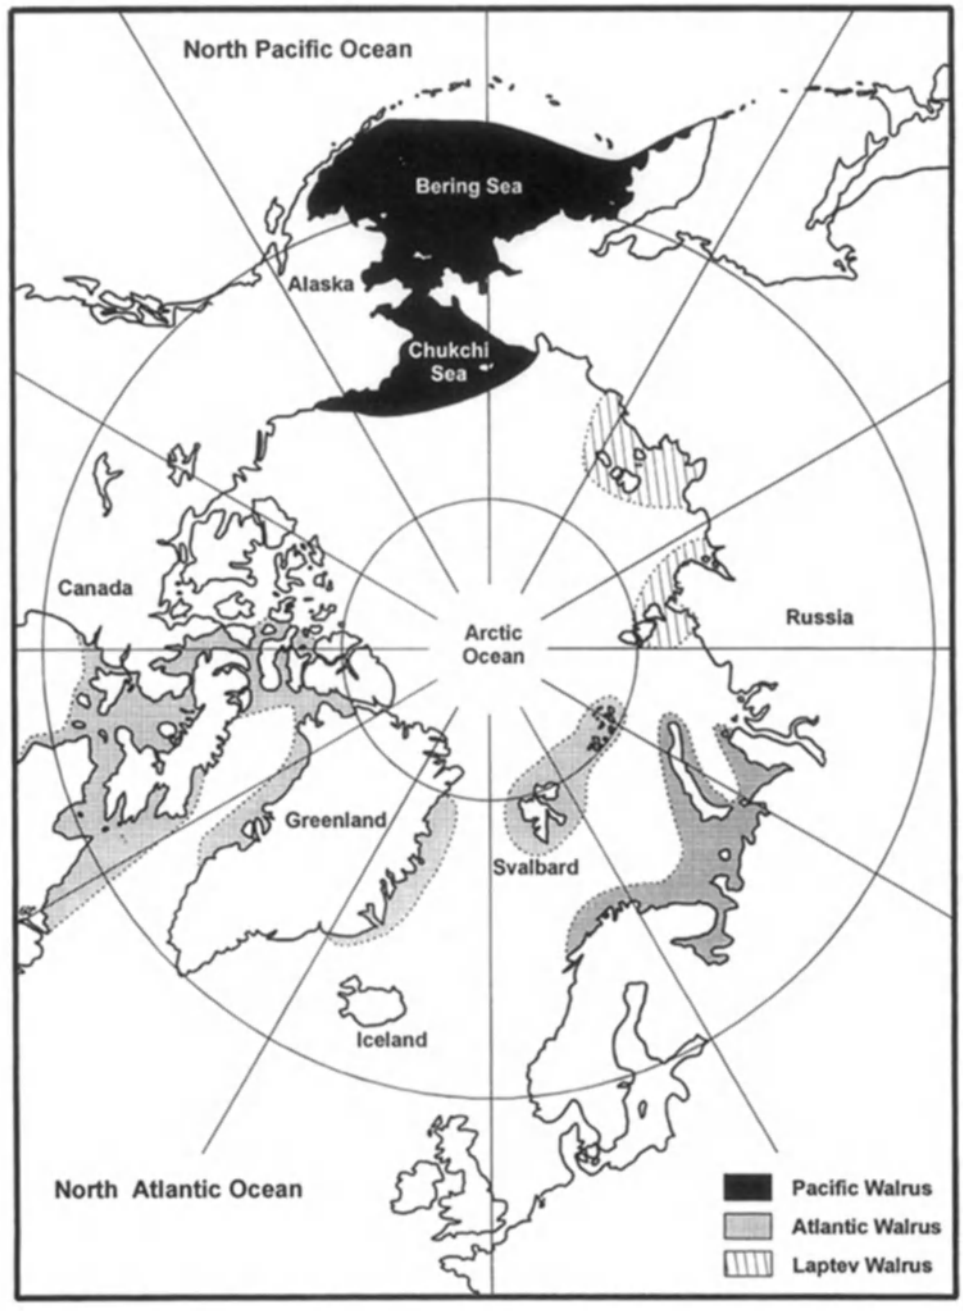

Figure 6 *Distribution of the three walrus subspecies (the recognition of the Laptev walrus as a subspecies is controversial).*

Atlantic walrus stocks were reduced greatly by intense exploitation in the 18th and 19th centuries by European whalers and sealers (for ivory, oil, and hides) and appears not to have recovered fully. The Pacific walrus population recovered from intense hunting, but, for unknown reasons, may have started to decline again.

Atlantic walruses are still hunted for subsistence by native people of Canada and Greenland. Pacific walruses are taken by indigenous peoples of Russia and the United States (Alaska) for the same purpose. Atlantic walruses are fully protected at Svalbard (since 1952) and in the western Russian Arctic (since 1956). Potential threats to walrus populations are overhunting, competition with shellfish fisheries, accidental bycatch by trawlers, POLLUTION (PCBs, heavy metals, nuclear radiation), waterborne NOISE at their foraging areas, aerial acoustic disturbances at their resting places (snowmobiles, aircraft, ships, oil, and gas exploration), and habitat destruction from bottom trawling.

VI. Behavior and Reproduction

Male and female walruses usually do not have contact with each other for most of the year, but animals of each sex congregate in large numbers in both winter and summer. Walruses seem to prefer being in groups. Walruses literally pile on top of each other (probably to conserve heat) in dense aggregations, and spend most of their haul-out time resting (Fig. 5). On land, they are usually in deep sleep and are difficult to wake up. They often lie upside down, perhaps to reduce the pressure on their lungs. In this position their tusks point upward, they can stretch their necks, and surplus ear wax can drain from their ears. Body size and tusk length play important roles in establishing the hierarchy at haul-out sites. The tusks are used for display and as weapons in fights between walruses and against polar bears (*Ursus maritimus*) and killer whales (*Orcinus orca*) (which may prey on walrus calves). They also aid in hauling out on ice floes and shores and serve to enlarge and keep open breathing holes in the ice. In addition they function to hold heads above water by resting on the edges of ice floes.

Several aerial acoustic signals are used in social context: barking, coughing, and roaring when excited, whistling by males during the reproductive period (source levels of around 120 dB re 1 pW have been recorded), and soft calls from the females toward their calves. Alarm calls and other calls of calves have been described. Underwater, bell-like sounds are produced by the air sacs of adult males.

Walruses have well-developed facial muscles and can make many facial expressions, which play a role in short-range COMMUNICATION.

Females generally begin to ovulate at around 7 years of age (but some ovulate already at the age of 5 years) and usually give birth for the first time at the age of 9 years. Males become sexually mature at between 7 and 10 years of age, but become physically and socially mature, and therefore able to mate, at 15 years. Walruses can reach an age of 30 to 40 years.

Adult male and female walruses congregate during the mating season (January–April). Walruses are polygynous. In the mating season, adult males fight intensively in the water, evidently in competition for display sites near females. During courtship, the male walrus emits a stereotyped sequence of underwater sounds consisting of taps, knocks, pulses, and bell-like sounds. This acoustic display probably serves as an advertisement to females and as a warning to other males. Females choose a mate from among the displaying males. Copulation usually occurs in the water, but has been observed to occur on land in captivity, although a pool was available.

After a gestation period of about 15 months (including a period of delayed implantation of 4–5 months), a single calf of around 60 kg and 120 cm in length is born in spring (April–early June). Calves can swim immediately and may sometimes be carried on their mothers' backs for a while. The coat of the calves is slate gray. They are suckled for at least a year (on land, on ice, and in the water) and are usually weaned gradually during their second year, when they begin to forage for invertebrates. Reproductive females can produce about one calf in 3 years. The calves remain near their mothers, in groups of adult females, for several years. Most calves are weaned by the age of 3 years, when males tend to join male herds. The high degree of maternal care and low predation rate result in low natural mortality in walrus calves. This probably allows the walrus to have fewer offspring then other pinnipeds, most of which produce a pup every year.

VII. Foraging Behavior

The diet of walruses consists mainly of benthic invertebrates. By far the most commonly eaten are bivalve mollusks, which are found buried in the sediment in high-density beds. How walruses find these beds is unknown. When they find a mollusk bed, they plough through the sediment with their snouts while swimming with their bodies at a 45° angle to the ocean floor to find prey items (Fig. 7). When foraging by plowing through the sea bed with its snout in search of invertebrates, the walrus uses its tusks and fore flippers as sleds while swimming with its hind flippers. Long furrows in the sediment have been observed in walrus feeding areas.

Once the walrus encounters a potential food item, it is identified quickly by the sensitive whiskers. If it is a bivalve mollusk, the foot or siphon is taken between the mobile lips, and by means of retraction of the large tongue, the soft parts are sucked from the shells and swallowed (Fig. 7). The empty shells are discarded and can be found on the ocean floor near the furrows. The walrus can produce strong water jets with its mouth to excavate its prey but can also remove sediment by producing strong water currents with movements of its fore flippers. The whiskers can be moved individually and are probably used as a tool to manipulate clams so that the foot or siphon is directed toward the walrus' mouth. Once a prey item is in front of the mouth, the tongue probably takes over as a touch and manipulation organ.

Compared to most other pinnipeds, walruses consume organisms that are small and low in the food chain. The large walrus has to consume many small organisms and must have a very

Figure 7 *Walruses foraging. They plow through the sediment on the ocean floor with their noses. When an object is encountered, it is identified with the whiskers. If it is a clam, the foot of the clam is taken between the lips, and the soft parts are sucked from the shell and swallowed. Drawing by Rijkent Vleeshouwer.*

efficient feeding method. In fact, walruses dive for up to 24 min (average around 5 min), usually spend 80% of that time on the bottom, and generally obtain 40–60 clams per dive. Dive times probably vary depending on water depth, prey type, and prey density. Adult walruses require on average about 25 kg of soft clam parts per day, and a walrus has been found with 6000 prey items in its stomach. In captivity, Pacific walruses sometimes eat up to 50 kg of fish per day. Walruses probably store extra fat during summer when they can exploit their inshore foraging grounds and use this during migration when they swim in waters that are too deep to contain their prey.

Uncommonly, individual walruses may take a vertebrate diet. These animals usually kill seals and cetaceans as well as scavenge on their carcasses, from which they suck the blubber and internal organs. Seal-eating walruses thus consume organisms that are higher in the food chain than those consumed by mollusk-eating walruses and therefore carry a relatively high concentration of heavy metals and PCBs. Walruses sometimes also capture and eat seabirds.

VIII. Sensory Systems

A. Vision

The walrus has well-developed extrinsic eye muscles. The orbital cavity is not closed on the dorsal side (Fig. 4). This allows the walrus binocular vision in the frontal and dorsal direction, as it can protrude its eyes, and does so mostly when excited (Fig. 2). The lack of a roof of the orbital cavity suggests that the eyes are vulnerable to mechanical injury. However, the walrus eye has strong retractor muscles. The eyes can be pulled deep into the orbital cavity for protection, and the eye opening can be closed with thick eyelids.

Blood vessels and surrounding fat probably serve to keep the eyes warm and functional under cold conditions. Under high light conditions, the pupil is a vertical slit; during moderate light levels, key-hole shaped; and under low light conditions, circular. Retinal anatomy suggests that the walrus has color vision, but because no psychophysical tests have been carried out, it is unclear which part of the spectrum it can detect. Visual acuity appears to be less than in other pinnipeds investigated so far, and the eyes of the walrus seem to be specialized for short-range VISION.

B. Touch

Because walruses dive up to 130 m and also at night, they often cannot always use vision to detect and process their prey. Instead, they use their sensitive mystacial vibrissae (whiskers). Each walrus has about 450 whiskers, which are highly innervated by sensory and motor nerves. The main sensory nerve (trigeminal nerve) is well developed, and the infraorbital foramen in the skull is proportionally large to accommodate it (Fig. 4). In contrast to most other pinnipeds, which probably use their whiskers to detect vibrations in the water, walruses use their whiskers to examine and manipulate small objects. In a psychophysical test, a captive walrus could distinguish a circle and a triangle that each had a surface area of 0.4 cm^2. The longer and thicker lateral whiskers are used mainly for the detection of objects, whereas the shorter and thinner ones near the mouth opening are used primarily for identification. The tip of the tongue also contains many mechanoreceptors and can be used to identify or reposition prey.

C. Olfaction

The behavior of the walrus on land and on ice suggests that it probably relies to a high degree on its sense of smell to obtain information about its surroundings. Anatomical evidence also suggests the importance of olfaction to walruses. They have large nares that can be closed during dives, and the nasal passage is highly vascularized so that air that passes through it can be heated. However, no conclusive psychophysical tests have been conducted on the olfactory sensitivity of the walrus.

D. Taste

Compared to many terrestrial mammals, the walrus has relatively few but large taste buds. However, not much is known about the taste abilities and discrimination in walruses. Anecdotal information on captive animals suggests that they are not very sensitive to (bitter) flavors that are disgusting to most terrestrial mammals.

E. Hearing

The walrus has limited ability to locate the source of airborne sounds, as evidenced by its lack of pinnae (Fig. 2). When the walrus is in air, sound reaches the tympanic membrane via a large cartilaginous outer ear tube. The aerial hearing has been tested and is less acute than that of humans in the frequency range tested (125 Hz–8 kHz).

When diving, the walrus closes its auditory meatus and hears by tissue conduction, probably mainly via the vascular lining of the outer ear tube. The underwater hearing range of the walrus has an upper frequency limit of 16 kHz.

IX. Captivity

The first walruses in captivity were in Denmark and Germany. Later, zoological parks in the Netherlands, United States, and Russia began keeping this species.

Captive walruses often ingest foreign objects that they cannot digest. A walrus can even die from consuming too many dead leaves that sometimes drop in pools in autumn. Another problem is the wearing down of tusks on the pool floor and walls, which, in severe cases, can cause root infections.

When cared for properly, walruses are friendly and easily TRAINED. They can perform for the public as well as in psychophysical research projects. Occasionally, males become difficult to handle after they reach maturity. Walruses can be kept in good health on a diet of whole fish, which they swallow without chewing. Reproduction in parks and zoos has improved in the last decade, but only a few calves have been raised by their mothers, as walrus mothers are very protective of their calves toward both conspecifics and humans. This causes the mother to neglect her calf (she spends more time defending the calf than nursing it) or reduces the production of milk. The main problem in the early years of husbandry was the lack of a good formula to raise calves that had been captured from the wild. This problem has been overcome, and calves from the wild or captive-born now can be hand-raised without nutritional deficiencies.

Weddell Seal

Leptonychotes weddellii

JEANETTE A. THOMAS
Western Illinois University, Moline

The Weddell seal has a circumpolar distribution around Antarctica. The seal hauls out through cracks in the fast ice formed from tidal action. This fast ice provides a stable platform for giving birth to pups, hauling out to avoid predators, and resting. Use of these traditional haul-out sites facilitated research on this species since the early 1960s. This species is the best studied of all Antarctic pinnipeds because the seals can be found reliably in breeding colonies at traditional sites. Several investigators maintained research programs near the U.S. bases at McMurdo Sound and Palmer Peninsula, the New Zealand Scott Base, and the Australian base at Davis Station.

I. Characters and Taxonomic Relationships

The Weddell seal belongs to the family Phocidae, subfamily Monacinae, and tribe Lobodontini. There is a single species within the genus *Leptonychotes*. The closest relatives are the other Antarctic seals in the tribe Lobodontini (i.e., crabeater, *Lobodon carcinophaga;* leopard, *Hydrurga leptonyx;* and Ross seals, *Ommatophoca rossii*) and the monk seals in the tribe Monachini (i.e., Caribbean, Mediterranean, and Hawaiian monk seals, *Monachus* spp.).

Weddell seals are black with grayish silver streaks, with individual variations. The adult fur does not have underfur. In pups, the lanugo is longer and thicker than adult fur and is shed by 44 days of age.

There is no dramatic SEXUAL DIMORPHISM in body size; males reach 2.5–2.9 m and females are 2.6–3.3 m in length. Weight ranges from 400 to 500 kg, with pregnant females attaining the greatest weights. At birth, pups weigh 22–29 kg and are about 1.5 m in length.

As with other phocids, the Weddell seal has a fusiform body shape and laboriously crawls on the belly or rolls to move on ice. It is not capable of upright stance or moving the hindlimbs forward. Under water, the Weddell seal propels itself easily by moving the hind flippers in a vertical plane. Manus are flippers and pes are fully webbed. The first metacarpal is noticeably larger than the others. Black claws on the front flippers are large and probably useful for gripping the ice or scratching. Claws on the hind flipper are reduced in size. The tail is distinct and free.

Its large brown eyes often have wet circles around them because of no lacrimal duct. It has a tapetum, which assists in seeing in low-light levels during the austral winter and deep dives. A nictitating membrane protects its eyes from blowing snow and allows its eyes to be open in salt water. The species has excellent VISION under water. Some accounts report that the seal remains in familiar, shallow water areas during the dark austral winter.

The external ear is absent and nothing is known about hearing abilities. The nostrils are oriented vertically and normally are closed, but open when the seal needs to respire. There are seven rows of mystacial vibrissae and superciliary whiskers that are smooth, not beaded as in some pinnipeds. The tip of the tongue is notched. Testes are abdominal, the penis is retractable, and there is a baculum. The uterus is bipartite. Two mammary glands are present and the milk is exceptionally high in fat and protein content.

It has a simple stomach and eats food whole, fish heads down first. It does not drink water, rather obtains water metabolically through diet. It has reniculate KIDNEYS adapted for conserving water and removing high salt loads. There are 34 chromosome pairs in this species.

The dental formula is 2/2, 1/1, 4/4, 1/1. The milk teeth disappear before or soon after birth. Cheek teeth have three points, but are not the exaggerated tricuspid structure of the crabeater and leopard seals. The outer incisors are larger and procumbent or project forward. The canines also are procumbent and, along with the last incisor, are used in "ice-sawing" behavior. The seal maintains circular breathing holes in the fast ice by turning within the hole and raking ice off the rim of the hole with its teeth. Such behavior allows the seals to maintain holes for breathing and hauling out throughout the year. However, ice-sawing behavior has prevented this species from being successfully maintained in captivity.

The seals stay warm through a heavy fur coat and thick layer of subcutaneous fat; their lower critical temperature is −40°C. Weddell seals can vasodilate to dissipate heat or vasoconstrict to conserve body heat. On a warm Antarctic day, steam can be seen rising from their bodies.

II. Distribution and Ecology

The subfamily Monachinae evolved in the North Atlantic during the Miocene. A fossil, *Homiphoca*, found off the South African coast could be the intermediate form between monk seals and Antarctic seals.

No systematic, large-scale population census studies have been conducted, so estimates in the literature are approximate. The Weddell seal is abundant; the estimated range is from 500,000 to 1 million seals. Occasionally, single seals are seen at sub-Antarctic islands, including South Shetlands, the South Orkneys, and South Georgia. Single wandering Weddell seals have been found in remote locations such as Heard, Kerguelen, Macquarie, Auckland, Juan Fernandez, and Falkland Islands, as well as Australia, New Zealand, Patagonia, and Uruguay.

There is no predictable migration in this species, but because there is a trend to move toward the fast ice, seals move northward before the onset of winter as the ice expands and southward during the summer to find pockets of fast ice.

Weddell seals are extremely good divers, commonly diving about 600 m, for up to 82 min (20 min is typical), ranging out to 5 km from a breathing hole and returning on a single dive. A great deal about their DIVING BEHAVIOR has been documented using satellite tags with time-depth recorders and video cameras attached to the seal's back. Before a dive, the seal exhales and the nostrils and mouth are closed. Seals usually make a series of short shallow dives before commencing on a longer dive. Swim speed is 8–12 km/hr and the descent rate for a dive is 35 m/min. During a dive, the Weddell seal collapses the lungs, compresses the trachea, shunts blood to extremities, drops the metabolic rate to 20% of the resting rate, and undergoes bradycardia from about 85 to 16 beats/min. The blood and muscles have a three to five times greater oxygen-carrying capacity than that of humans.

III. Behavior and Life History

Mother Weddell seals return to tidal cracks each austral spring and give birth to pups from late September to early November. Typically, a single pup is born, but twins have been observed and even an albino pup was reported. A few mothers have pups in isolation from other seals, but most give birth in colonies of up to 50 mothers with pups. Mothers and pups maintain individual spacing when hauled out on ice (Fig. 1). When disturbed, mothers vocalize to intruders. Pups nurse for a 7- to 8-week period, gaining almost 2 kg per day. At weaning, pups weigh about 125 kg and mothers have lost nearly that amount of weight because they do not forage during the nursing period. Pups are first enticed into the water by their mother's calling at 10–14 days of age. Pups struggle to swim and stay under the water, popping to the ice surface. Some pups die in the breathing holes, not being able to crawl out of the slippery, steep hole. Mothers and older pups go into the water progressively more often as the pup grows. They exhibit a distinct diel pattern of haul-out, with most seals hauling out in the colony for several hours around midday.

Adult males are not tolerated on the ice in maternal colonies. Only occasionally is a nonbreeding, adult male seen in the periphery of the colony. Soon after females give birth, adult males arrive and compete for underwater territories aligned beneath the tidal cracks. Males patrol using loud (up to 193 dB re 1 μPa) trills to advertise and defend their underwater territories, which cover an area 15–50 m wide by 50–400 m long. Sometimes bloody fights occur between males under water and even continue onto the ice, with the loser evicted from the territory. The underwater repertoire of Weddell seals is elaborate, including some 34 sound types near McMurdo Sound. GEOGRAPHIC VARIATIONS in the

Figure 1 *A mother Weddell seal calls to her pup to maintain spacing within a breeding colony.*

repertoire were documented among McMurdo Sound, Palmer Peninsula, and Davis Station seals. Their sounds are some of the longest among marine mammals, ranging up to 70.0 sec, with 75 calls given per minute by a colony during the height of the breeding season. Mating takes place in water, with about 80% of females becoming pregnant, at least in the McMurdo Sound area. Once the pups wean, the mother enters the water to feed and mating occurs within a male's territory. Adult seals molt after mating. Implantation of the blastocyst is delayed until mid-January. Because of delayed implantation, pups are born the following spring at approximately the same time of year. Delayed implantation allows the mother to molt, feed, and recover from the dramatic weight loss associated with lactation before another fetus starts to develop.

About the time the last pup in the colony weans in mid-December the fast ice breaks up, adults disperse, and newly weaned pups are left to fend for themselves. Some data taken from pups with transmitters indicated pups feed near shore on small fish such as *Pleurograma* spp.

Subadult seals are rarely seen in breeding colonies. They tend to congregate in large groups near the ice edge. Subadult Weddell seals do not exhibit the scars from leopard seal predation that are seen on crabeater seals. However, killer whales are known to take Weddell seals of all ages. When killer whales (*Orcinus orca*) and leopard seals move into areas of Weddell seals, *Leptonychotes* suddenly and dramatically stops calling underwater, perhaps to avoid detection.

An adult seal was seen to surface in a breathing hole with a large, 100-pound, Antarctic cod (*Dissostichus mawsoni*) in its mouth. Video footage from a camera mounted on a seal's back recorded an episode of capture of this large prey. If a fish hides in a crevice, the seal blows bubbles into the water to chase the fish into an open area.

IV. Interactions with Humans

The seals have little fear of humans because there are no natural land predators like the (Arctic) polar bears. James Weddell reported seeing and hearing this seal during his Antarctic expeditions and the seal was named after him. A detailed description of this species was recorded in 1907 by E. A. Wilson while he spent a 2-year period at Hut Point on Captain R. F. Scott's first expedition to Antarctica. The expedition reportedly took seals to feed their sled dogs. In 1934–1935, A. A. Lindsey studied Weddell seals at the Bay of Whales as part of Admiral R. E. Byrd's second Antarctic expedition and specimens now are deposited in the Field Museum of Natural History in Chicago. In 1940, G. C. L. Bertram studied the species as part of the British expedition to the Antarctic Peninsula. J. Sapin-Jaloustre (1952) studied the seal at Terre Adelie Land as part of a French expedition. Some early specimens were collected by the Little America explorers. In 1957, the International Geophysical Year established the importance of conservation and research in the Antarctic. The Antarctic treaty was signed in 1961, establishing the protection of the species and its habitat. During the 1970s and 1980s, inhabitants of the New Zealand station in McMurdo Sound took Weddell seals to feed their sled dogs over the winter. This practice has stopped. Otherwise, there is no record of extensive harvest of this species.

Whale Lice

CARL J. PFEIFFER
Virginia Polytechnic Institute and State University, Blacksburg

Whale lice (cyamids) are crustacean ectoparasites living on the skin of some species of cetaceans. Whale lice remain among some of the world's biologically most specialized but least understood crustaceans. The current lack

of knowledge about these animals undoubtedly stems from the fact that their natural habitat is limited to the skin surface of primarily slow-moving baleen whales, which themselves are difficult to study because they are generally submerged and constantly moving. Accordingly, it is very difficult for scientists to observe, in their natural setting and over extended periods of time, the behavior and biologic processes of whale lice. Some features have been learned, however, by a small number of scientists who have studied these interesting crustaceans for over a century, and the following brief account reviews these data.

I. Classification

Whale lice are actually not lice but perhaps they acquired this nickname in the 1800s from whalers who noticed that they crawled, presumably as parasites, on the surface of the whale's skin and that their size, in proportion to that of a great whale, was comparable to the size of louse on a human or dog. Whale lice are arthropods of the subphylum Crustaca, class Malacostraca, order Amphipoda, family Cyamidae, and genus *Cyamus*. As such they are closely related to other more commonly observed amphipods such as sand hoppers and caprellids, i.e., common marine peracarids. Altogether there are more than 5000 crustacean species, but only 23 known species of whale lice or cyamids. At least 15 of these comprise the genus Cyamus. Because the practice of WHALING has such a long history, cyamids were historically documented early, including *Cyamus ceti* by Linné in 1758, a genus described further by Latreille in 1796. A number of species were classified in the 1800s, including *C. ovalis* in 1834, *C. delphini* in 1836, *C. boopis* in 1870, and *C. scammoni* in 1872, and these cyamids were found on southern right whales (*Eubalaena australis*), humpback (*Megaptera novaeangliae*), gray (*Eschrichtius robustus*), and other large whales. Species names have occasionally been revised for cyamids and new species were discovered even late in the 20th century, such as the two new cyamids reported on one of the large beaked whales, the Baird's beaked whale *Berardius bairdii* (Waller, 1989). Genus names for cyamids have also been changed over time and the earlier genus *Paracyamus* is no longer considered valid.

II. General Ecology and Morphology of Cyamids

Although information does not exist on the early development of cyamids, their evolution has undoubtedly been closely coupled with the long evolution of cetaceans, which first began around 55 million years ago when terrestrial species returned to the marine environment as precursors of the modern whales. Thus, modern cyamids show little resemblance to other crustaceans and have become greatly specialized for their parasitic and lifelong relationship to whales. They have a high degree of host specificity to whales, and one species, *Cyamus boopis*, is found only on humpback whales and another species, *C. scammoni*, only occurs on the gray whale. Some other species of whale lice overlap their residence on two to four species of whales. The two isolated Arctic odontocetes, beluga whales (*Delphinapterus leucas*) and narwhals (*Monodon monoceros*), each share the same two cyamids, *C. monodontis* and *C. nodosus*. Table I summarizes the cetacean distribution of cyamids. Cyamids are unable to swim freely in the sea or from whale to whale at any of their developmental stages. Accordingly, they die if they lose their foothold on their host, but can be transferred from cetacean mother to calf or during cetacean mating. Although details on the number of juvenile stages that occur prior to adulthood are not yet established for cyamids, Leung (1976) has estimated that at least seven to eight instar stages exist for *C. scammoni* of the gray whale.

Although the general gross body structure of cyamids has been described elsewhere (Margolis, 1955; Leung, 1967; Berzin and Vlasova, 1982), very few studies have been directed toward the microscopic anatomy of cyamids. Early work on the musculature and very recent work (Levin and Pfeiffer, 1999) on cyamid ocular structure have been reported. Their small, paired eyes appear almost rudimentary. However, ultrastructural analysis of these photoreceptors for *C. ceti* has revealed well-developed sensory organs with each eye containing about 50 visual ommatidial units and an overall organization similar to other amphipod compound eyes. The exoskeleton of cyamids consists of a chitinous cuticle that is similar to that typically observed for other crustaceans. It has an exocuticle with multiple microfibrillar lamellae and an endocuticle traversed by both pore canals and dense fibers, as revealed by electron microscopy (Pfeiffer and Viers, 1998).

Cyamids are SEXUALLY DIMORPHIC. The males are larger and, depending on species, adult cyamids usually range from approximately 6 to 19 mm in length. The most striking features of their appearance are their marked degree of segmentation and prominent gnathopods, or legs, with large dactyli, or hooks, that assure firm attachment to the host. The body is flattened and divided into a small cephalic–cephalon or head with paired, minute eyes, and segmented pereion or body to which are attached two pairs of gills and four pairs of gnathopod-type appendages. Figures 1 and 2 illustrate examples of the general body structure for *C. ovalis* and *C. scammoni*, respectively.

Cyamids are mostly found on those areas of the whale surface most protected from the turbulence of water flow, which on baleen whales include regions around barnacles, skin folds or ventral grooves of the head, protected zones around the blowholes, eyes, and flippers, margins of the lips, on callosities, wounds, and genital slit. In those species of whales that serve as host to several species of cyamids, there may be differences in the spatial distributions of the different species of whale lice, and within one species of cyamid the reproductive status and sex of the cyamid may alter the spatial distribution (Rice and Wolman, 1971; Balbuena and Raga, 1991; Rowntree, 1996). Whale lice do move around on their cetacean hosts; in the case of *C. boopis* of the humpback whale, the larger males may carry their smaller female mates and, in an artificial aquarium setting, were observed to walk at a rate of 4.5 m/hr (Rowntree, 1996).

Whale lice breathe by means of two pairs of external gills, which are much reduced in size in early juvenile stages. It has been reported that they can live for up to 3 days out of an aquatic environment, such as on a stranded whale, suggesting that they can also rely on integumentary respiration (Leung, 1976).

TABLE 1
Distribution of Cyamid Species on Cetaceans[a]

Host	*Whale lice*
Mysticeti	
Bowhead whale, *Balaena mysticetus*	*Cyamus ceti*
Right whales, *Eubalaena* spp.	*C. ceti, C. erraticus, C. gracilis, C. ovalis, C. catadontis*
Gray whale, *Eschrichtius, robustus*	*C. ceti, C. kessleri, C. scammoni*
Blue whale, *Balaenoptera musculus*	*C. balaenopterae, C. bahamondei*
Humpback whale, *Megaptera novaeangliae*	*C. boopis, C. elongatus*
Common minke whale, *B. acutorostrata*	*C. balaenopterae*
Fin whale, *B. physalus*	*C. balaenopterae, C. bahamondei*
Odonticeti	
Sperm whale, *Physeter macrocephalus*	*C. ovalis, C. catadontis, C. bahamondei, Isocyanus delphini, Neocyanus physeteris*
Baird's beaked whale, *Benardius bairdii*	*Platycyamus flaviscutatus, C. orubraedon*
Beluga, *Delphinapteris leucas*	*C. monodontis, C. nodosus*
Narwhal, *Monodon monoceros*	*C. monodontis, C. nodosus*
Northern and southern bottlenose whales, *Hyperoodon* spp.	*C. thompsoni, I. delphini*
Long-finned pilot whale, *Globicephala melas*	*Isocyamus delphini*
Short-finned pilot whale, *G. macrorhynchus*	*I. delphini*
Short-beaked common dolphin, *Delphinus delphis*	*I. delphini, syncyamus pseudorcae*
Risso's dolphin, *Grampus griseus*	*I. delphini*
White-beaked dolphin, *Lagenorhynchus albirostris*	*I. delphini, Scutocyamus parvus*
Harbor porpoise, *Phocoena phocoena*	*I. delphini*
Killer whale, *Orcinus orca*	*I. delphini, C. antarcticensis*
False killer whale, *Pseudorca crassidens*	*I. delphini, S. pseudorcae*
Rough-toothed dolphin, *Steno bredanensis*	*I. delphini*
Gervais' beaked whale, *Mesoplodon densirostris*	*I. delphini*
Pantropical spotted dolphin, *Stenella attenuata*	*Syncyamus* sp.
Striped dolphin, *S. coeruleoalba*	*Syncyamus* sp.
Spinner dolphin, *S. longirostris*	*Syncyamus* sp.
Common bottlenose dolphin, *Tursiops truncatus*	*Syncyamus* sp.

III. Feeding Habits of Cyamids

It was speculated for a long time that whale lice fed on whale skin and hence they were deemed ectoparasites. Some workers suggested that they might be omnivorous and ingest algal filaments or suspended materials or plankton in the water near their attachment site. However, their mouth parts are very small compared to their body size and they do not possess claws such as some other crustaceans or food-gathering cirri such as some predatory, sessile crustacean barnacles (Pfeiffer and Lowe, 1989). Cyamids have poorly developed paired mandibles and incisor processes with strong chitinous teeth that appear well suited for piercing and scraping skin. Rowntree (1983) showed that the color of intestinal contents of cyamids from humpback whales matched the skin color (black or white) from which the cyamids were collected. More recent conclusive evidence has proven that whale skin is a principal dietary material of cyamids. Both electron microscopic proof of whale skin keratinocytes within the upper digestive tract of cyamids and stable isotope evidence have shown that the dietary staple of whale lice is whale skin. Analysis of stable carbon and nitrogen isotope ratios from cyamids and skin from six species of whales have shown that the cyamic ratios closely matched those of whale skin, but not those of zooplankton from the sea where the cyamids and whales reside (Schell *et al.*, 1999). Also supporting this conclusion is the evidence of direct damage to the skin by whale lice (Leung, 1976). Thus, cyamids have evolved into the only obligate parasites among the amphipods in distinction to other amphipods, such as caprellids, which are predatory and feed on diatoms, other crustaceans, and so on.

IV. Reproduction in Cyamids

Reproductive and mating behavior has been less studied in cyamids than in other amphipods and, indeed, has not been investigated in most cyamid species. The males practice mate guarding and consorts are formed, but there appears to be less aggressive territorialism than is evident with some other amphipods. Little is known about cyamid copulation. There is morphological evidence of a secretory product being released on the cuticular surface of amphipods (Pfeiffer and Viers, 1998), but it is not known if this serves as a pheromone-type attrac-

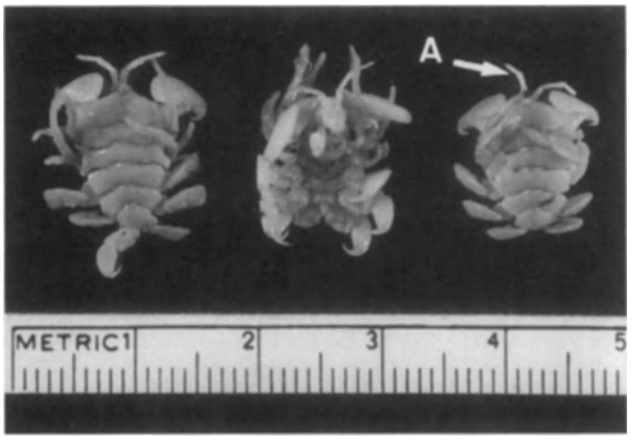

Figure 1 *Three specimens of* Cyamus ovalis *showing ventral surface on center specimen. The head region faces the top. Note segmented body and antennae (A).*

tant for mates or serves some other function. Electron microscopic evidence has shown many tactile sensillae on the antennae and head regions of cyamids, some of which are also likely chemoreceptors. One can question if they always sit on their sole food source, why they have evolved so many sensillae. Female cyamids have a brood pouch (four-plated) or marsupium on their ventral surface, and both unhatched eggs and juvenile whale lice are retained in this cavity. A clutch of 1078 eggs was observed in the marsupium of one female *C. scammoni* (Leung, 1976). The young cyamids measure only about 0.5 mm in length and crawl in and out of the marsupium during development and remain there for at least 2–3 months, when they become about 1.5 mm in length for *C. scammoni*. Several workers have proposed a seasonality for cyamid reproduction, but partly due to the migratory habits of whales, detailed data are not yet available on potential seasonal changes.

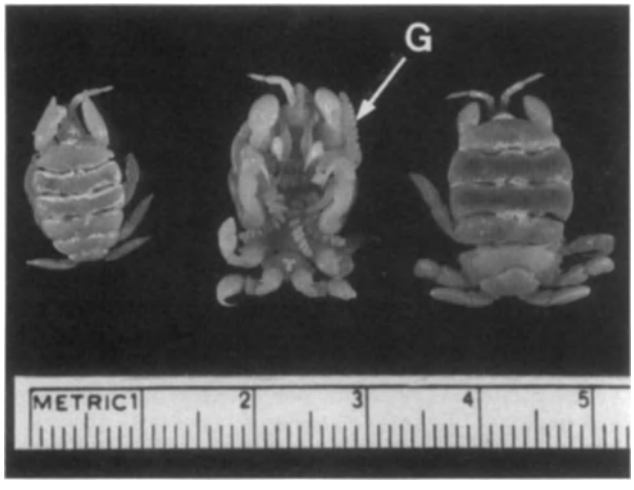

Figure 2 *Three specimens of* Cyamus scammoni *showing ventral surface on center specimen. The gills (G) of this species have a spiral shape.*

Whale Watching

Erich Hoyt
North Berwick, Scotland, United Kingdom

Whale watching is the human activity of encountering cetaceans in their natural habitat. It can be for scientific, educational, and/or recreational purposes

(sometimes all three). Mostly, whale watching refers to a commercial enterprise, although it is sometimes undertaken privately. The wide variety of whale watching activities includes tours lasting from 1 hr to 2 weeks using platforms ranging from kayaks to cruise ships, from land points including cliffs and beaches, from sea planes and helicopters in the air, as well as SWIMMING and diving activities in which the whale watcher enters the water with cetaceans. Whale watching grew out of the traditions of bird watching and, to a lesser extent, other forms of land-based wildlife watching. To this day, the better whale and dolphin trips include sea birds, seals, turtles, and other marine fauna in order to appeal to more people as well as to give a well-rounded ecological interpretation.

I. The Birth of Whale Watching

The species originally responsible for the development of whale watching was the gray whale (*Eschrichtius robustus*). Beginning in the mid-1940s, students from Scripps Institution of Oceanography, led by Carl L. Hubbs, began participating in annual gray whale counts from university buildings such as Ritter Hall and from coastal headlands and lighthouses. In 1950, the Cabrillo National Monument in San Diego was converted into a public land-based whale watch lookout, attracting 10,000 people the first winter. Year after year, more and more people came to watch whales.

In 1955, the first commercial whale watch operation charged $1 USD to see gray whales on their winter MIGRATION off San Diego. Although the gray whales passed close to shore, the boat tours allowed a closer look. Beginning in 1959, Raymond M. Gilmore, a U.S. Fish and Wildlife Service biologist who had taken over the gray whale counting chores from Carl Hubbs, began serving as the first naturalist on whale watch trips out of San Diego. Through the 1960s, boat tours and land-based whale watching spread slowly up the coast of California to Oregon and Washington, although southern California remained the heart of the industry. In 1972, the first long-range commercial whale watch trip to the Mexican calving lagoons was organized out of San Diego.

In 1971, the Montreal Zoological Society began offering whale watch tours to go down the St. Lawrence River in Canada to see mainly fin (*Balaenoptera physalus*) and minke whales (*Balaenoptera acutorostrata*) and belugas (*Delphinapterus leucas*). This was the first commercial trip on the east coast of North America. These trips became an annual event.

It was the HUMPBACK WHALE (*Megaptera novaeangliae*), however, that really made commercial whale watching into a big industry. Humpback whales tend to be much more active at and above the surface than gray or other whales, frequently breaching clear of the water—ideal for whale watchers wanting photographs. Added to this is the phenomenon of "friendly" behavior—the tendency of certain individual humpback whales to habituate to the presence of whale watch boats and to approach them regularly. This behavior, first observed commonly in humpback whales, has now also been found in certain gray whales, particularly in the mating and calving lagoons of Baja California, Mexico; in certain minke whales; and in orcas (*Orcinus orca*) and bottlenose dolphins (*Tursiops truncatus*), among others.

In New England and Hawaii, tours to see humpbacks began in 1975. For more than a decade before, the Wailupe Whale Watchers, a local club on Oahu, sponsored loosely organized, infrequent tours, but when whale watching began in earnest from Lahaina on Maui, where the humpbacks were more numerous and accessible, it immediately became the center of the humpback whale-watch industry in the Pacific. Most of the Hawaiian tours were strictly commercial.

In New England, however, operators established their own brand of commercial whale watching with strong scientific and educational components—naturalists on every trip who were often working researchers. Educational programs to introduce school children to wild cetaceans—begun in southern California by such groups as the American Cetacean Society—were expanded in New England. Within a decade, the New England industry would attract even more participants than Californian and Hawaiian whale watching. New England was fortunate to have humpback whales on the feeding grounds centered on Stellwagen Bank, 7 miles north of the tip of Cape Cod, as well as North Atlantic right (*Eubalaena glacialis*), fin, minke, and sometimes long-finned pilot whales (*Globicephala melas*), and Atlantic white-sided dolphins (*Lagenorhynchus acutus*). From a commercial point of view, Stellwagen Bank was ideally located close to the large population centers of the U.S. east coast.

II. Scientific Whale Watching

Whale watching for the purposes of research can be traced back to Aristotle, who spent time on boats and with fishermen in the Aegean Sea. In "Historia Animalium," Aristotle writes that the fishermen would nick the tails of the dolphins and that they could tell them apart. This practice foreshadows the studying of animals by watching them, a key feature of the ethology approach for studying birds and land animals pioneered by Konrad Lorenz, Niko Tinbergen, and others. It took longer to attempt such research with cetaceans because of the greater difficulties of approaching close and conducting research at sea. The photographic identification (photo ID) research of cetaceans began in the early 1970s with humpback whales in the North Pacific and North Atlantic, gray whales and killer whales in the eastern North Pacific, and southern right whales (*E. australis*) and bottlenose dolphins off Argentina.

A successful partnership between science and commercial whale watching began in Provincetown, Massachusetts, in 1975, when Al Avellar of the *Dolphin* fleet asked Charles Stormy Mayo to be his naturalist. Mayo soon saw the possibilities for using the boat as a platform for studying whales. He set up the Center for Coastal Studies as a research and educational institution, and the close ties with commercial whale watching have been maintained ever since.

The arrangement works as follows: The Center provides naturalist guides for the *Dolphin* fleet. They are paid a modest amount for helping to direct the boat to the whales, presenting an informal educational lecture, and answering questions. The Center sells T-shirts and other merchandise on board. Most important, Center researchers can conduct their own photo ID research, and often collect other data. Sometimes more than one researcher will come aboard to ensure the maximum use of boat time.

This key partnership between science and commerce has determined the course of whale watching, as well as the practice of whale research, throughout southern New England. As of 1995, 18 of the 21 whale watching operators that mainly go to the Stellwagen Bank area had naturalists guiding boats and lecturing whale watchers, while 10 operations were taking and contributing ID photos. Despite the competitive atmosphere of commercial whale watching in New England, the researchers and their representative institutions have cooperated in setting up the North Atlantic Humpback Whale Catalogue—a photo catalogue and data base covering more than 10,000 individual whales. As a measure of the scientific value of whale watching, at least 30 published papers in refereed journals have come largely from research aboard whale watching boats on Stellwagen Bank.

The New England model of successful whale watching and research, like Yankee WHALING from an earlier century, has had an impact on the development of whale watching in locales as diverse as the Gulf of St. Lawrence in Quebec, northern Norway, and Dominica in the eastern Caribbean. Of course, a large part of scientific research on cetaceans does not lend itself to being conducted from commercial whale watch trips (such as transect surveys, biopsy darting, and collecting skin and fecal samples). In some cases the research and commercial enterprise operate separately, using different boats and personnel, but the commercial operation supports or contributes to the research. In several areas, whale watch operations have discovered new populations of cetaceans, accessible for study. In all, whale watching worldwide has led to at least 50 cetacean photo-ID programs supported in part or conducted aboard commercial whale watch boats. This has contributed to considerable public support for research through much greater familiarity with research programs.

III. The Growth of Commercial Whale Watching

The value of whale watching in 1981 was estimated to be $4.1 million USD in direct revenues and $14 million in total revenues (including travel, accommodation, food, and souvenirs), based on approximately 400,000 boat-based whale watchers. By 1988, these numbers had expanded by more than three times, with the industry still based largely in New England and California with a small amount in Canada, Mexico, and the U.S. northwest (see Table I).

In the late 1980s, whale watching began to spread rapidly to other parts of the world. Between 1987 and 1991, new whale watch industries started up in the Canary Islands, the Azores, Belize, Costa Rica, Dominica, Italy, Madagascar, and New Zealand, while existing industries expanded rapidly in Argentina, Australia, South Africa, and in parts of Canada. The diverse opportunities for whale watching included boat tours to view rare species (Haviside's dolphins, *Cephalorhynchus heavisidii*, in South Africa), observing sperm whales, *Physeter macrocephalus*, from the air (New Zealand), land-based whale watching of southern right whales (South Africa, Australia), and glimpsing various beaked whales in the Azores and the Bahamas. However, by the 1990s whale watching meant for the most part going to sea on large, fast, comfortable purpose-built ships that could take 150 to 400 people to see the whales and get them back to the dock in 2–4 hr.

TABLE I
Estimated Growth of Whale Watching Worldwide

Year[a]	*No. of whale watchers*	*Direct expenditures USD*[b]	*Total expenditures USD*[c]
1981	400,000[d]	$4.1 million	$14 million
1988	1,500,000[d]	$11–16 million	$38.5–56 million
1991	4,046,957[e]	$77.0 million	$317.9 million
1994	5,425,506[e]	$122.4 million	$504.3 million
1998	9,020,196[e]	$299.5 million	$1049.0 million

[d]Estimates made by author based on direct revenues; does not include land-based whale watchers.
[e]Includes land-based whale watchers.

During this same period, whale watching became important in Norway and Japan, two countries with strong whaling interests. In both countries, the number of whale watchers increased rapidly year by year until, in 1998, Norway had more than 21,000 whale watchers spending $6.9 million USD, while more than 102,000 whale watchers in 27 Japanese communities spent $32.4 million USD. Norway's whale watching industry has about a dozen operators working from four communities and offering sperm and other whales from May to September or killer whales in October and early November; whale watchers (visitors) primarily come from other European countries. Japan's whale watching industry, however, is a 99% domestic industry with diverse attractions including Bryde's whales (*Balaenoptera edeni*) and sperm whales at several warm-water locations from Shikoku Island and adjacent Honshu; humpback whales in tropical Okinawa and Ogasawara, both island groups off southern Japan; and minke whales, Dall's porpoises (*Phocoenoides dalli*), and Pacific white-sided dolphins (*Lagenorhynchus obliquidens*) from Hokkaido in the north, as well as multiple locations for watching and swimming with bottlenose (*Tursiops truncatus*) and other dolphins off southern and eastern central Japan.

In the late 1990s, Iceland, with accessible populations of blue, fin, humpback, and minke whales, as well as orcas, became the fastest growing whale-watch destination in Europe, with eight communities hosting more than 30,000 whale watchers in 1998 with total expenditures of more than $6.4 million USD. In 1998, three countries attracted more than a million whale watchers per year: the United States, Canada, and Spain's Canary Islands. According to the most recent worldwide figures (1998), more than 9 million people are going whale watching in 87 countries and overseas territories and spending more than $1 billion USD (see Table I).

IV. Whale Watching Conflicts and Regulations

Such explosive whale watching growth has led to management problems. Typical scenarios include too many boats on the water in a limited area, too many close approaches and sometimes collisions with cetaceans, strain on the infrastructure of local communities from too many visitors, and a lack of guidelines or regulations and/or enforcement of them.

Some operators have formed associations to devise self-imposed guidelines, but most have waited for researchers or NGOs to suggest guidelines or for government to try to impose regulations. Yet even where regulations do exist, enforcement tends to be minimal or absent. In the United States, however, cases have been prosecuted with substantial fines levied against boat operators, as well as researchers and photographers, who approach too close or too aggressively to whales or who operate without a permit. In Hawaii, a film maker was fined for harrassing whales when his close-up underwater footage of a pilot whale (*Globicephala macrorhynchus*) mouthing a woman researcher was sold to television.

In 1983, the first whale-watch fatality occurred when a mature gray whale overturned a small boat in Scammons Lagoon, Mexico, killing two tourists. Until 1995, this was the only fatal whale watch accident. Then, all in the space of a year, in the Dominican Republic, the upper deck of a crowded boat collapsed after being hit by a wave, killing one tourist and injuring others, whereas in Kaikoura, New Zealand, a boat overturned, fatally trapping a person underneath. In the same period, on a sightseeing trip near Baffin Island in the Canadian Arctic, a surfacing whale overturned an 18-foot boat and four tourists died of exposure. Only their guide survived. He was wearing a survival suit.

The number of injuries and fatalities is small considering the millions of people who go whale watching every year. Whale watching is by and large safe for both whales and people. Boats have been accidentally overturned by whales, but more accidents have happened due to problems with the boats themselves or with overloading—things that are not specific to whale watching but could happen as part of any marine tourism. Indeed, most if not all of the accidents to date could have been avoided with due care and precaution.

Perhaps the greatest concern for safety is for the tours involving swimming or diving with cetaceans. Even these have a good safety record with thousands of encounters with dolphins in such places as New Zealand, the Bahamas, and Japan. These generally well-regulated enterprises maintain a strict protocol of no touching and approaching the cetaceans. However, some have suggested that swimming with cetaceans should be limited to certain dolphin populations or known individual animals and that experienced researchers should be present as guides to help interpret behavior and ensure safety. Swimming with whales, such as humpback whales on their mating grounds where there is surface active behavior, is potentially more dangerous to humans; despite criticism it continues in several areas of the world, and it remains controversial.

There are other concerns about whale watching—the amount of time boats stay around the same whales, day in and day out, and the presence of boats on critical mating and calving grounds—but little can be determined with certainty until more time passes and more research is done.

V. Whale Watching and Conservation

In 1983, the INTERNATIONAL WHALING COMMISSION (IWC) cosponsored the "Whales Alive" conference in Boston, Massachusetts, which looked at "nonlethal" uses of whales, but it was not until 10 years later, in 1993, that the IWC adopted a whale watching resolution prepared by the Whale and Dolphin Conservation Society and successfully proposed by the United Kingdom at the IWC annual general meeting in Kyoto, Japan. The underlying strength of the argument that the IWC should become involved in whale watching was that, since the IWC moratorium on whaling, the most prevalent "use" of cetaceans among IWC members has been whale watching. However, despite majority agreement on the relevance of whale watching to the IWC, delegates from Japan have repeatedly stated that the IWC has "no competence" concerning whale watching matters.

Beginning in 1995, a series of international workshops, organized by the International Fund for Animal Welfare (IFAW), with assistance from the Whale and Dolphin Conservation Society, Tethys Research Institute, World Wide Fund for Nature, and others, have brought together more than a hundred

cetacean experts from some 25 countries to explore the socioeconomic, educational, and legal aspects of whale watching, as well as the scientific aspects of management and the special aspects of watching SPERM WHALES.

The first of these, the seminal Scientific Aspects of Managing Whale Matching workshop, held in Italy, determined that, to date, there were no detrimental long-term effects on cetacean populations attributable to boat-, air-, or land-based whale watching. The participants took the view, however, that the individual welfare of wild cetaceans needs to be considered as well as the health of populations. Even if whale watching is not lessening a whale's ability to survive, it might be diminishing a whale's quality of life. Also, participants acknowledged that long-term effects might not show up for some time. Of course, it is important to recognize human socioeconomic needs when determining whale watching regulations and policy. The workshop recommended a precautionary approach to management with a periodic review of regulations based on continuing research and monitoring into possible effects on cetaceans (sample guidelines for boat operators are provided in Table II).

The overall impact of this and later workshops is still in the early stages, but they have focused the debate on the future of whale watching, pointing out that better regulations were needed as well as enforcement, that whale watching had substantial unrealized potential in terms of education and science, and that, economically, whale watching was worth far more than had previously been determined, although some values were difficult to measure in terms of dollars. A more detailed and complete valuation of whale watching is now underway in a number of communities.

Perhaps the most valuable legacy of whale watching has been the building of a constituency out of the general public that is interested in and sympathetic to marine mammals, the sea, and marine conservation. The designation of Stellwagen Bank as a U.S. National Marine Sanctuary in 1993 was largely the result of public interest in whales in New England and in the northeastern United States through whale watching. Several million people encountered whales in the wild between 1975 and 1992, saw the research being conducted on whale watching boats, and learned about the whales and problems of the sea, which led to overwhelming popular support for the sanctuary.

Since the late 1980s in most areas of the world, however, whale watching has been much less educational (see Table III). A 1998 world SURVEY of whale watch operations found that only 35% of all operators had enlisted naturalists to guide their trips. In terms of the scientific content, about 9% of operators worldwide have researchers or naturalists on board who conduct regular photo ID and other research as part of their trips, whereas 57% never conduct scientific research or even offer information to scientists. Most operations were strictly commercial ventures. Clearly, a great deal more could be done to encourage whale watching tours to offer the maximum benefits to local communities and regions in terms of education, science, and conservation, as well as tourism dollars, while at the same time protecting the whales and ensuring that they will remain in coastal waters and accessible to whale watchers for generations to come.

TABLE II
Brief, Useful Guidelines for Boat Operators[a,b]

1. Do not pursue, overtake, head-off, or encircle cetaceans or cause groups to separate
2. Never approach whales/dolphins head on
3. Avoid sudden changes in noise level (gear shifts, avoid reverse unless necessary to back away slowly from a surfacing whale or dolphin group)
4. Reduce speeds in areas where whales may be sighted: approach and leave whales cautiously and slowly
5. Extreme caution is required when the following is present: (1) feeding whales, (2) cow/calf pairs and juveniles, (3) resting, (4) breeding or rowdy and/or (5) socially active groups. Cetaceans behaving in these ways are particularly sensitive to disturbance and may be vulnerable to collisions

[a]Adapted from IFAW, WWF, and WDCS (1997), used with permission.
[b]This is not a complete list covering every situation but is meant to provide some general suggestions and overall direction for the use of operators offering whale watch tours as well as wildlife managers who are establishing guidelines or regulations on whale watching.

TABLE III
Educational Values of Whale Watching[a]

1. Whales are emblems for promoting awareness of endangered species and habitat protection
2. Whale watching provides the opportunity for people across all ages and cultures to become familiar with environmental issues and to become involved in conservation efforts on a personal, local, regional, national, and international level
3. The development of education programs forges links between the whale watch industry and local communities as well as building bridges between the general public and scientific communities
4. Natural history knowledge gained through whale watching has intrinsic value
5. Whale watching provides an opportunity to observe animals in the wild, transmitting factual information and dispelling myths
6. Whale watching is a model for marine educational programs in adventure travel and ecotourism
7. Whale watching provides the opportunity for appreciation and understanding of local history, culture, and environment

[a]Adapted from IFAW, WWF, and WDCS (1997), used with permission.

Whaling

Whaling, Early and Aboriginal

Richard Ellis
American Museum of Natural History, New York, New York

Jenkins (1921) writes, "Although the general opinion is that the Basques were the earliest whalers, Noel de la Moriniere says that this is a misapprehension and that the Northmen were really the first in the field." He says that a man called "Ochther" hunted whales and walruses beyond the North Cape, but then he notes that "there is no evidence that it developed into a regular fishery such as that of the Basques."

His "Ochther" was Othere (or Ottar), a Norseman in the service of King Alfred of Wessex around the year 890 A.D. Alfred (called Alfred the Great) is known for his defense of England against the marauding Danes, and also for the initiation of the *Anglo-Saxon Chronicle*, the first history of England. (Our word "whale" comes from the Anglo-Saxon *hwael*, which means "wheel," and probably refers to the shape of the whale's back as it rolls in the water.) Alfred translated many Latin texts, including the one that concerns us here, a description of Europe by one Orosius, who lived four centuries before. To the work of Orosius, Alfred added a description of the northern voyage of Othere, wherein was described the whale and walrus hunting of a northern people known as the Biarmians. From the location (the White Sea in northern Russia), and description of the whales hunted ("50 ells" in length, which by one calculation works out to 187 feet), it would appear that the larger ones—whose size was greatly exaggerated—were bowheads, whereas Othere's "horsewhales" were walruses (*Odobenus rosmarus*). In the history of British *Voyages and Discoveries* compiled in the 16th century, Richard Hakluyt, a diplomat and scholar, wrote that the principal purpose of Ochther's expedition was "to increase the knowledge and discovery of these coasts and countries, for the more commodity of fishing for horse-whales, which have in their teeth bones of great price and excellency: whereof he brought some at his return unto the King. Their skins are also very good to make cables for ships, and so used."

In medieval Scandinavia, whales were very much a part of the lives of the people and were therefore incorporated into their literature. A 13th-century Icelandic account known as *Konungs skuggsjá* (*Speculum Regale* in Latin; *Konegspiel* in German; "King's Mirror" in English) describes the whales that are found off Iceland and includes such mysterious creatures as the horse whale, the red whale, and the pig whale, but also discusses recognizable species, such as the killer whale (*Orcinus orca*), the narwhal (*Monodon monoceros*), and the sperm whale (*Physeter macrocephalus*). The right whale (*Eubalaena glacialis*) is described thus:

> People say it does not eat any food except darkness and the rain which falls on the sea. And when it is caught and its intestines opened, nothing unclean is found in its stomach as would be in other fish that eat food, because its stomach is clean and empty. It cannot open its mouth easily, because the baleen that grows there rise up in the mouth when it is opened, and often causes its death because it cannot shut its mouth. It does no harm to ships: it has no teeth, and is a fat fish and edible.

There is an almost complete lack of information on Norse whaling, but the waters in which they sailed were then (and are still) among the whale-richest in the world. There are right whales, humpbacks (*Megaptera novaeangliae*), fin whales (*Balaenoptera physalus*), sperm whales, belugas (*Delphinapterus leucas*), narwhals, pilot whales (*Globicephata melas*) and various species of dolphins in the cold, productive waters of the North Atlantic. The Norse sagas are silent on the subject of whales and whaling, but it would be hard to imagine these hardy seafarers ignoring a plentiful source of food and oil as they plied the otherwise inhospitable seas around Iceland, Greenland, and Labrador. There are references, however, to battles royal between various "families" as they dispute the ownership of whale

carcasses, which indicates the importance of whales—at least of dead whales—in the lives of the early Norsemen. They left no tryworks and their settlements provide no trace of harpoons or lances, but there are tantalizing hints of Norse whaling in some of the more recent discussions. In his 1928 *History of Whaling*, Sydney Harmer says, "The Icelanders seem to have engaged in whaling . . . and the whale known as 'Slettibaka' . . . is believed to have been the Biscay whale." (The modern Icelandic for the right whale is *sletbag*, which means "smooth back.")

I. Early Icelandic Whaling

Iceland's early history is to be found in the sagas, tales of the exploits of the island's early heroes. The Vikings of Norway evidently brought to Iceland knowledge of the techniques employed in driving whales (probably pilot whales) into the fjords for slaughter. There are occasional mentions of disputes over stranded whales in the sagas, but as far as we know, there was no active whale fishery. An Icelandic bestiary from about 1200 describes some of the whales (but not accurately enough for modern cetologists to identify them as to species), and the *Konungs skuggsjá* lists no fewer than 21 sea creatures, some of which can be referred to living whales, dolphins, and pinnipeds, and some of which—mermaids and mermen, for example—are clearly mythological.

In a 17th-century work by an Icelander named Jon Gudmundsson, there is a list of the various whales that might be found in Icelandic waters, including the sperm whale (*Burhvalur*), the narwhal (*Náhvalur*), the right whale (*Slettbakur*), the fin whale (*Geirreydur*), and the blue whale, *B. musculus* (*Steypireydur*). With the exception of the "right whale," which probably refers to the bowhead (*Balaena mysticetus*) and was hunted to extinction in the region after this publication appeared, all these whales can still be seen off Iceland. Also included was something that the author referred to as *Sandloegja*, which has been translated as "sandlier," i.e., one that lies in the sand. Each of the just-mentioned whales is illustrated, so there is little doubt as to its identification. The description of the *Sandloegja* is accompanied by a picture of a whale that has not been seen in the Atlantic since commercial whaling began, and if the interpretation is correct, it depicts the only whale to have become extinct in recent history.

The California gray whale (*Eschrichtius robustus*) is well known from the North Pacific, where it makes the celebrated round-trip migration from Alaska to Baja California. It was the object of an intense fishery in the 19th century, which nearly eliminated the species. Fossil and subfossil remains of a similar—if not identical—species have been found in western Europe (Sweden, England, and the Netherlands) and on the east coast of North America from New Jersey to South Carolina. From the evidence, it appears that there was also an Atlantic gray whale, which probably maintained similar habits to its Pacific cousin: it fed in cold northern waters (perhaps Iceland and Greenland) and then moved south (Spain, France, England?) to breed and calve. With the exception of the fossil evidence, the only clues to the identity of this whale are found in the work by Gudmundsson and in a debatable reference in a New England work of 1725, where Paul Dudley describes the "scrag whale" with characteristics that are not applicable to any other species except the gray whale. Whether hunted or occasionally appearing on the beach, the gray whale apparently should be listed in the Icelandic cetacean fauna, even though no living Icelander has ever seen one in his own country. (In his analysis of the whales of the *Konungs skuggsjá*, Ian Whitaker writes that "the gray whale was hunted in the Atlantic between 1100 and 1200, although it has not been found there since the 18th Century." He is unable to correlate this species with any of the 19th-century Icelandic names, although he indicates that there are two "unallocated" names, which translate as "hog whale" and "shield whale.")

Whales were caught by the Norwegians off the Tromsø coast as early as the 9th or 10th century. The oil was used for lighting and the baleen for jewelry, coopering, and boatbuilding. "But," as C. B. Hawes wrote in 1924, "with a lamentable lack of foresight, the earliest whaling captains neglected to enlist the services of scholars and historians," so much of the story of early Norse whaling has to be left to conjecture.

One of those who did a lot of conjecturing was Ivan Sanderson. Trained as a zoologist, Sanderson was particularly interested in bizarre phenomena, such as the abdominable snowman and the Loch Ness monster. He wrote several books on zoological and cryptozoological subjects, but he will probably be best remembered for his *Follow the Whale*, which was published in 1956. In this book, along with some rather good accounts of the biology of whales and some excellent maps, he recreates the lives of whalers of the past and the present, "corralling the forgotten and more neglected aspects of whaling history and the new discoveries about the whales themselves, and weaving them into a continuous web of narrative." One of these "neglected aspects" is Norse whaling history, but despite the lack of documentation, Sanderson devotes a whole chapter to the subject, fictionalizing what could not otherwise be ascertained. He has the Norsemen under "Thorvald the Long" trapping sei whales (*B. borealis*) in the fjords of Norway at an unspecified time, along with "Biarni the Yellow standing in the bow holding a trumpet of cow's horn in his hand." He also recounts an Icelandic saga of 1100 A.D., which contains "a delightful passage in which we are told of the stranding of a large rorqual at Rifsker in Iceland and how all the important people who were able went to it." The documentation for this is sparse, but there can be no question that the Norsemen, ranging the North Atlantic from Finnmark to Iceland and from Greenland to North America, had to have encountered whales. Whether they killed the whales in an organized fashion or took them incidentally to their Viking and settlement forays may never be known. They did hunt walruses for their skin and ivory tusks, and narwhals for their spiraled ivory tooth, which was passed off as the horn of the fabled unicorn.

II. Basque Whaling

As far as we can tell, the first western people to hunt large whales in an organized and intentional manner were the Basques. As far back as records go—and even further, perhaps as far back as the Stone Age—these men were hunting whales. In his 1820 *Account of the Arctic Regions*, William Scoresby suggests that "the Biscayans were the first who exercised their courage in waging a war of death with the whales," but he attributes their motivation to the protection of their fishing nets, which "would nat-

urally suggest the necessity of driving these intruding monsters from their coasts." Whatever their reasons, the Basques became the paradigms of the whaling industry, establishing the modus operandi that would characterize the industry for another thousand years. "Historians have only recently begun to realize," wrote Farley Mowat, "that it was the Basques who lit the flame that was eventually to consume the mighty hosts of the whale nations." They discovered the "resource," exploited it, and then pursued it so vigorously that it was uneconomical to continue. They probably took their first whales in the shallows, and then, like the bay whalers who were to follow their lead all around the world, realized that it was considerably more expeditious to go after the whales rather than wait for the whales to come to them. The Basques may also have contributed to the only cetacean extinction in recorded history.

Somewhere around 1000 A.D., these intrepid hunters of the Bay of Biscay began the slow but systematic eradication of the whales that came into the protected bays in the shadow of the Pyrenees. Obviously the Basques did not wait for the first millennium to end before beginning their whaling, but most authors cite this as approximately the time they began. (Ommanney writes: "The industry, founded on the Biscay Right whale, was fully developed by the twelfth century but probably dated from much earlier, possibly from the tenth century when the Basques may have learned the craft from Norse whalers.") The Belgian historian W. M. A. De Smet has searched the literature for references to European whaling *before* the Basques and writes, "Only a few authors are aware of the fact that whaling existed in still earlier days in other European seas, and that it was practiced in the North Sea and the English Channel during the Middle Ages, certainly from the 9th century onward." Although the species of whale in these early instances was rarely recorded, the likelihood is that it was the right whale that was hunted in the North Sea, and perhaps the gray whale, although the precise date of the disappearance of the Atlantic gray is still being debated.

De Smet cites several instances in which whale meat is mentioned in early texts and suggests that "it is clear from the regularity with which whale meat occurred in these markets that it cannot have come from stranded animals alone and there must have been regular landings." After providing for themselves, the enterprising Basques established markets for the meat and blubber, and even had "consulates" in Holland, Denmark, and England to encourage sales. In French, the blubber was known as *lard de carime*, which means "lenten fat," and Europeans were allowed to eat it on designated meatless calendar days. The oil was used for lighting and the manufacture of soap, wool, leather, and paint; the meat was fed to the poor and to the ships' crews; the baleen as put to all sorts of uses (including being shredded into plumes for the decoration of knight's helmets); the vertebrae were used for seats; and the ribs were employed as fence pickets and beams for cheap housing. The tongue was considered a particular delicacy and was reserved for the clergy and royalty.

In the unregulated (and largely undocumented) confusion of the Middle Ages, small pockets of Basques lived along the shores of the Bay of Biscay, speaking their own language, about which a contemporaneous cleric wrote, "The Basques speak among themselves in a tongue they say they understand but I frankly do not believe it." In their strongholds in the crook of the elbow of the Iberian peninsula, they were isolated from the turmoil of land wars, fiercely intent upon self-preservation, and coincidentally upon the pursuit of the large black whales (which they called *sarda*) that arrived every autumn in their offshore waters.

It is likely that they also hunted the Atlantic gray whale, although there is no evidence to support this supposition. There *is*, however, considerable evidence that the Atlantic gray whale (which was called *otta sotta*) was present in the Atlantic during the days of Basque whaling. Remains have been found on both sides of the ocean: in England, Holland, and Sweden in the east and from New York and New Jersey to North Carolina in the west. An account discovered by Fraser suggests that a gray whale (called *sandloegia* by the Icelanders) existed as recently as 1640 in the waters off Iceland. With nothing more than the absence of gray whales to substantiate his claim, Mowat writes "that by as early as the fourteenth century, the otta sotta had been hunted to virtual extinction in European waters." In their 1984 study of the Atlantic gray whale, Mead and Mitchell recognized only Fraser's *sandloegia*[1]; a 1725 description of the "scrag whale" by Paul Dudley, Esq.[2]; and the 1611 instructions given by the directors of the Muscovy Company to Thomas Edge[3] as "reliable records of gray whales in the North Atlantic." There are no more gray whales in the Atlantic, and while this unfortunate state of affairs might not be directly attributable to the Basques, it is not unreasonable to assign them some part in the disappearance of these whales.

For many years, the most comprehensive study on the subject of Basque whaling was that written by Sir Clements Markham and published in 1881. While writing a study of William Baffin, he learned "that the first English whaling vessels were in the habit of shipping a boat's crew of Basques to harpoon the whales," so he began to investigate and ended up in Spain. He found that King Sancho the Wise of Navarre had granted petitions to the city of San Sebastian in the year 1150 for the warehousing of certain commodities, among which were *boquinas-barbas de ballenas*, plates of whalebone. Markham traced the fishery through the records of various cities and towns (he found the "Casa de Ballenas" in Asturias) and acknowledged that it was the Basques who taught the British how to kill whales. He sums up the Basque contribution as follows: "Of course the English, in due time, learnt to strike the whales themselves; but the Basques were their instructors; and it is therefore to this noble race that we owe the foundations of our whaling trade."

More recently, the Spanish cetologist Alex Aguilar searched the records for written documentation of Basque whaling and has discovered a reference from Bayona, in the Gulf of Biscay, that

[1]"Good eating. It has whiter baleen plates, which project from the upper jaw instead of teeth, as in all other baleen whales, which will be discussed later. It is very tenacious of life and can come to land to lie as a seal like to rest the whole day, But in sand it never breaks up."

[2]"The Scrag whale is near a-kin to the Fin-Back, but instead of a Fin on his Back, the Ridge of the After-part of his back is scragged with a half Dozen Knobs or Knuckles; he is nearest the right Whale in Figure and for Quantity of Oil; his Bone is white, but won't split."

[3]"The fourth sort of whale is called Otta Sotta, and it is of the same colour its the Trumpa having finnes in his mouth all white ball white but not above a yard long, being thicker than the Trumpa but not so long. He yeeldes the best oyle but not above 30 hogs' heads."

dates from the year 1059. From the remains of cetaceans examined at some of the settlements on the shore of the Cantabrian Sea (off the northern coast of Spain), it has been suggested that the Basques occasionally hunted sperm whales, but the predominant object of their fishery was the right whale. Ancient whaling bases have been found along the length of this coastline, which encompasses the provinces of Galicia, Asturias, Santander, and the heart of the Spanish Basque country, Guizpuzcoa. From the western tip of northern Spain the sites have Spanish names (Camariñas, Malpica, Antrellusa, Llanes), but as we move eastward, toward the Basque settlements on the Bay of Biscay, the names take on a decidedly Basque flavor: Lequeitio, Ondarroa, Guetaria, and Zarauz. Aguilar quotes several sources (including Markham) for the number of whales killed at Lequeitio from 1517 to 1662, and produces a total of some 62 whales, adults and young, from incomplete records, for a provisional average of a little more than 2 whales per year. Occasional records for Guetaria from 1699 to 1789 provide even lower numbers, suggesting that the Biscayan right whales were on the decline by the 18th century.

Along the French and Spanish Biscayan coasts, there are several towns and villages whose seals and coats-of-arms depict whale-fishers, including Bermeo, Ondarroa, Motrico, and Fuenterrabia in Spain and Biarritz, Hendaye, and Guethary in France. Jenkins writes, "in this fishery the Bayonnais took part, and it is one of the most interesting features in the ancient records of the town of Bayonne." For several centuries, the Basques of Biarritz, St. Jean-de-Luz, Bayonne, San Sebastian, and other towns killed the *sarda* in their inshore and offshore waters. This activity did not go unnoticed by the tax collectors. In 1197, King John of England (acting as the Duke of Guienne) collected a tax on the first two whales taken at Biarritz. In 1261, all whales taken at Bayonne were tithed, a continuation of an earlier, voluntary gift of all whales' tongues to the Church. The kings of Castile and Navarre also extracted taxes from the whalers, often in the form of meat or whalebone. Under a 1324 edict known as *De Praerogativa Regis* (The Royal Prerogative), Edward II of England (1307–1327) collected a duty on every whale captured in British waters, and his successors continued to claim the "royal fish" as Crown property.

To this day, we do not know whence the Basques came, or from whom they were descended. (Their blood type distinguishes them from the French and the Spanish, and biologically as well as linguistically they appear to be distinct from any other people now in existence.) As far as we can ascertain from the scanty records and the ruined stone watchtowers (known as *vigías*) that still stand overlooking the bays, they pursued the right whale. (In 1928, Sydney Harmer wrote, "A watchman who tried to use [the towers] for their original purpose would now have an unprofitable occupation, and he would not be likely to see a single whale of this species during his lifetime.")

Even more significantly, the Basques are said to have invented the on-board try-works, where whales could be processed at sea, avoiding the time-consuming and arduous process of towing the carcass to shore and then winching it up on the beach for rendering. According to Jenkins, this distinction belongs to "a captain of Cibourre named François Sopite," but surprisingly, in a book heavily footnoted with obscure references, this important fact goes undocumented. In Sanderson's *Follow the Whale*, however, a whole chapter is devoted to a recreation of Sopite's accomplishments, including a description of him standing "silently on the poop with his hands behind his back peering out from under his curious floppy black hat." Sanderson seems to have consulted many of the same references listed by Jenkins, but he does not tell us where the hat comes from or how he knows that Sopite was "smiling wryly" at the success of his experiment. Up to that time, whales were flensed and tried-out on shore, which meant that the whalers could never roam too far from their home ports. As we shall see, however, Sopite's "invention" may have been the invention of some creative authors, as real evidence of the Basque whalers has been uncovered, and there is no indication whatsoever of on-board tryworks.

Even though the hunters never took very many whales in a given season, the right whale (known as the Biscayan whale to distinguish it from the Greenland right whale or bowhead) disappeared from Biscayan waters, and the Basques had to look farther afield for oil and bone. (Clements Markham, in his study of Basque whaling history, has written that each of the whaling villages may have taken no more than a couple of whales per year. This would not be enough to decimate the population, but it is possible that the disturbance caused by the whalers drove the whales to other, less perilous breeding grounds.)

From Iberia, Basque fisherman crossed the North Atlantic seeking new grounds. Some evidence indicates that they may have fished the Labrador–Newfoundland grounds as early as the 14th century but were driven off by the local Eskimos. The vessels that they used were not known until recently, when a Canadian archaeologist named Selma Barkham followed up some vague hints in the historical records of Labrador and, with the help of divers, located the wrecks of several Basque ships in the area known as Red Bay. Found sitting on the bottom of the bay were the remains of a three-masted 90-foot galleon, which is believed to have sunk in a storm in 1565, and the complete hull of one of the frail chalupas.[4] On two of Red Bay's smaller islands, workers found unmistakable evidence of tryworks, where the blubber of the whales was rendered into oil. Because this endeavor took place between the years 1560 and 1570 (ascertained from documents examined in Spanish archives by Barkham), it would appear that Sopite's "invention" of on-board tryworks was either apocryphal or somehow did not extend to the whaling operation at Red Bay.

As the Basques enlarged the scope of their search for whales to the vicinity of Newfoundland and Labrador, they may well have been the first Europeans to fish the Greenland coasts and the Grand Banks, two of the richest cod-fishing grounds in the world. Upon landing, they predated John Cabot and Jacques Cartier, the "official" discoverers of the land known as Terranova. In their pursuit of the sea's bounty, the adventurous Basques visited Ireland, Iceland, Greenland, and evidently sailed as far north as Spitsbergen. They also crossed the Atlantic to find the right whales that inhabited the inshore waters of Newfoundland

[4]A *chalupa* (in French a *chaloupe* and in the British fishery a *shallop*) was a 25-foot-long whaleboat, rowed by six oarsmen, from which the whale was harpooned and towed to shore.

and Labrador, but it is unlikely that they made these voyages without island hopping across the perimeter of the North Atlantic, much as the Norse had done before them.

Examination of the bones at Red Bay indicate that bowheads were also processed there by the Basques. This location is considerably south of the known range of the bowhead, which inhabits—or inhabited—eastern Arctic waters and the Bering Sea. (It is likely that the Basques took bowheads farther north and then brought them back for processing, thereby accounting for bowhead bones in a region where bowheads are not known to have lived.) There are no records of Basques hunting humpbacks, but these whales are found off the Canadian Maritime coasts and Greenland.

The rich days of Newfoundland and Labrador whaling ended for the Basques as the 16th century ended. The destruction of the Spanish Armada in 1588 meant that Spanish ships of war could no longer protect fishing fleets so far from home, and the Basque whalers ventured across the Atlantic unprotected. They had established shore stations at Tadoussac and Sept-Iles on the St. Lawrence, where they hunted humpbacks and probably belugas. By 1738 the last Basques had left Canada. Why bother with the transatlantic crossings and hostile North Americans when there were fat Greenland whales for the taking in Spitsbergen? The Basques participated in the early Dutch and British expeditions in Spitsbergen, bringing with them 500 years of whaling experience.

Six Basque harpooners from St.-Jean-de-Luz were part of the crew of the first Muscovy Company expedition to Spitsbergen in 1611. In the early years of the Greenland Fishery (Barendsz had named the Spitsbergen islands "Greenland" when he discovered them in 1596 because he believed they were an extension of the island of that name), the Basques sold their services to whoever was willing to pay, but in addition to their participation in the Dutch/British rivalry, the Spanish Basques also sent their own ships to the northern ice in 1613. No sooner had the Spanish tried to join the fishery on their own than James I of England issued the Muscovy Company an exclusive charter to fish the waters of Spitsbergen, to which the Dutch countered in 1614 by forming their own Noordsche Compagnie with the same objectives.

Although the Spanish Basques had the experience and the expertise, they did not have the naval power to back up their claims, and as the Dutch and the British competed for supremacy in Spitsbergen (the Dutch eventually won the battle because of their more effective management and business practices, but in the end, everybody lost, because they ran out of whales), the Basques faded into whaling oblivion. As time and progress passed them by, their domestic whaling capabilities diminished accordingly. According to J.-P. Proulx, when a whale stranded at St. Jean-de-Luz in 1764, the hunters could only find old and rusty implements with which to cut it up.

In many respects, the Basques were the advance guard of what would eventually become an all-out war on the whales, but in those relatively uncomplicated times, they were only aware of the nutritional needs that could be fulfilled by the taking of these large, inoffensive animals. They would, however, establish a pattern with regard to the right whale fishery that would serve as an example for virtually every nation that followed their lead: they took the females and calves, as they were the most accessible, and by so doing guaranteed the catastrophic degeneration of the breeding population. In a review of available data, Aguilar estimates that during the period 1530 to 1610, Basque whalers might have taken as many as 40,000 right whales. Medieval Europeans probably did not have much time to ponder the effects of their actions on future generations, however; certainly not on future generations of whales.

III. The Beginning of Japanese Whaling

Halfway around the world, at approximately the same time that the Basques were winding down their whale fishery, the Japanese were gearing up for what would become one of the predominant whaling enterprises of modern times. As with most early whaling exercises, it began humbly, with people waiting for the occasional whale to wash up, but soon lookouts were being stationed on shore to watch for passing right, sperm, gray, or humpback whales. At first, the villagers drove the whales into a bay and closed the mouth off with a net, but then it occurred to them that they could go after the whales with nets rather than waiting for them in a bay or lagoon. Somewhere around 1675, Yoriharu Wada, now recognized as the "founder" of Japanese net whaling, organized the boatmen and harpooners of Taiji into whaling crews, and when a whale was spotted by lookouts on shore, the whalers went off in pursuit. The whales were herded into the nets by their would-be captors, who then killed them with repeated lance thrusts. The carcass was towed to shore and winched up on to the beach for processing. Unlike their European contemporaries—say in the Greenland bowhead fishery—Japanese whalers wasted no part of the whale. They ate the meat, used the oil for soap and lamps, but they also mixed the oil with vinegar to make an insecticide for rice paddies. The bones were crushed and used for fertilizer; the baleen for fans, fishing rods, lantern handles, and puppet strings. Medicines were made from various internal organs, and predictably, the penis was dried and pulverized into a tonic. The entrails were boiled into soup, and it is said that the membranes of the heart were made into drum heads. The Japanese continued this form of highly efficient, highly ritualized whaling until well into the 19th century, when Yankee sperm whalers, searching the Seven Seas for sperm whales, arrived on the "Japan Grounds" and, by their presence and influence, changed Japanese whaling irrevocably.

IV. Aboriginal Whaling

In its early chapters, the story of whaling was a simple one: man against whale. Very infrequently, the whale won. (In "Moby Dick," despite the rage of Captain Ahab and the skill of the harpooners, the white whale triumphs.) With the passage of time, the hunters changed the nature of the hunt and turned it into an industry. The hunted whales remained unevenly matched with their opponents; all they had was the hope of escape in the depth and expanse of the ocean. As the industry grew more economically important, technological innovations were introduced that altered the odds greatly. The introduction of diesel catcher boats, exploding harpoons, spotter planes,

sonar, and asdic changed the nature of the hunt greatly. No longer remotely equitable, it was not even a hunt any more, but a highly mechanized business. The whale had as much of a fighting chance as a tree had against a chain saw.

There are only a few places in the world where people still *hunt* whales. The Caribbean island of Bequia in the Grenadines, for example, has a relic humpback whale fishery that the Bequians learned from Yankee whalers in the 19th century. The Inuit of Greenland hunt minke whales and humpbacks (they are given a quota by the International Whaling Commission), as well as belugas and narwhals, which are considered "small cetaceans" and are not under the jurisdiction of the IWC. Alaskan Inuit "hunt" the bowheads that annually pass their North Slope villages, but because of the complexities of politics and other factors, they have upgraded their weaponry to the point where once again, the whale has hardly any chance of escaping. There are only a couple of places where whaling takes place in a thoroughly primitive manner (and completely unregulated by the IWC): one is in Indonesia and the other is the island of Camiguin in the Philippines, where Bryde's whales are the target of opportunity.

Lomblen, also known as Lembata, is one of a group of islands that make up the Sunda Archipelago (*Nusa Tenggara Timur* to the Indonesians), which includes the large islands of Timor and Flores, as well as the smaller Solor, Adonara, Pantar, and Alor. Lomblen/Lembata is only one of the 13,000 islands that comprise the 3000-mile-long country of Indonesia, but there is something very special about this island. On its southern shore is Lamalarep, one of the few whaling villages in all Indonesia. Lamalarep is the poorest village on the island because it has virtually no industry or agriculture other than whaling, and the success rate of the whalers seems to be rather low. They might capture a whale on 3 trips out of 10; to put it another way, 70% of their trips are unsuccessful. The villagers of Lamalarep do not eat the bulk of the whale meat they take, but dry it in the sun and trade it to other villages for vegetables.

In June of 1979, a research team was sent to Lamalarep by the World Wildlife Fund to investigate the whaling activities there. Unfortunately, on July 17, a giant tsunami inundated Lomblen, causing over 700 casualties and destroying the villages of Wai Teba and Sara Puka. The investigators all survived, however, and remained on Lomblen for 3 weeks. On July 26, on nearby Rote Island, a "giant shark" (species unidentified) was found with the body of what was thought to be a Lomblen fisherman in its stomach. (It is likely that the shark ate one of the victims of the tsunami, rather than taking a swimmer or a fisherman.)

At dawn the Lamalarep fleet sets out for a day's HUNTING. They may roam as far as 17 miles offshore, but the whales are usually found closer to the islands. The boats (known as *peledang*) are about 30 feet long and brightly painted, often with vigilant eyes on the bows. No nails are used in their construction, only wooden pegs; and the sails are patchwork rattan, a single gaff-rigged square sail for each boat. A crew of 10 to 15 men rows (or sails, if the winds are favorable) the boat out to the whaling grounds, south of the islands in the Savu Sea. They look for the forward-angled spouts of the largest of the toothed whales, the sperm, which they call *ikan pails* in Bahasa Indonesia. (In the language of the islands that was employed before the introduction of this *lingua franca* by President Sukarno, the sperm whale was known as *kotan klema.*) During the 10 weeks that the World Wildlife Fund researchers kept records, the whalers of Lamalarep took sperm whales, killer whales (*Orcinus orca*), pilot whales (*Globicephala macrorhynchus*), and several species of dolphins. Traditionally, the whalers of Lamalarep do not hunt baleen whales. Although the men of Lamalarep are considered whalers, they will also harpoon any large fish, ray, or turtle that they encounter, including sharks, marlin, and ocean sunfish.

The whalers of the island are divided into hereditary "corporations," each of which owns a whaling vessel. The vessels—and their names—are passed down from generation to generation, so when a given boat wears out, the next one built by that clan is given the same name.

When a whale is sighted, the *peledang* crews row stealthily upon it, douse the sail, and, because they are Christians, they whisper a communal *Pater Noster* for their own protection. The harpooner stands on a narrow platform with his bamboo-shafted harpoon poised. At the critical moment, when he is within striking range of the wrinkled, humped back of the whale, the harpooner launches not only the harpoon, but *himself* through the air, using his strength and his weight to drive the iron deep into the flesh of the whale.

As the whale is slowed or stopped by the pain of the harpoon in its back, another harpooner throws himself on the whale and, if necessary, another. The iron must be planted in exactly the right place to kill the whale; otherwise the fragile *peledang* will be towed for miles as the whale pulls the whalers on the Indonesian equivalent of the "Nantucket sleigh ride." There are stories of boats being towed all the way to Timor by a maddened whale. (In fact, there are many tales about maddened whales in the Timor Sea. One of the most notorious of all these was a bull sperm whale named "Timor Jack," who savaged whaleboats for years until he was taken by setting out a barrel on a line which he attacked, allowing whalers to lance him.) Or the whale will dive, pulling the line out rapidly and, unless it is cut, pulling the boat down with it. If the right spot is pierced (the heart or lungs), the whale will spout blood from its blowhole and expire quickly. The dead whale is towed back to the village where it is butchered.

There is a complex system for dividing up the meat of a whale in which the carcass is portioned out according to rank in the clan and the village. The meat is eaten or bartered to other villages; the oil is used for lamps. The men of the village may carve patterns onto the teeth, like scrimshanders everywhere.

The villagers of Lamalarep kill between 30 and 50 sperm whales every year. They do not take the large bulls because the big males do not visit these waters. They cannot eat all the meat, so they barter it in neighboring villages. This is in direct contravention of the regulations of the INTERNATIONAL WHALING COMMISSION, but because Indonesia is not a signatory to the Whaling Convention, the IWC regulations are difficult—if not impossible—to apply.

Whaling, Traditional

Richard Ellis

American Museum of Natural History, New York, New York

Beginning with the Basques around 1000 A.D., there were many people that conducted whale hunts, but until the advent of industrial whaling in the 20th century, there had never been a whale hunt as organized and systematic as the sperm whale fishery out of New England. Founded in the Massachusetts villages of Nantucket and New Bedford, the technology of sperm whale hunting—and the profits to be derived therefrom—spread to many locations in and around New England, including Albany, Long Island, New Jersey, Delaware, and Maine. The whale fishery—immortalized in Herman Melville's 1851 *Moby Dick*—had an enormous effect on the economy of the recently founded United States, and the whale ships spread American culture and customs around the world. The focus here will be on the well-documented American whale fishery, but similar fisheries were operated by many other nations during the same period.

I. The Beginning of Sperm Whaling

The story of Christopher Hussey's accidental encounter with a school of sperm whales (*Physeter macrocephalus*) has been told so often that it probably no longer matters whether it really happened. In 1712, Captain Hussey was cruising the Massachusetts coast (there were still right whales, *Eubalaena glacialis*, to be caught at that time) when an unexpected storm blew him out to sea. When the clouds cleared, he saw the spouts of whales, but they were forward-angled blows, not the vertical, paired plumes of right whales. Hussey managed to capture one of these unusual animals and towed it back to Nantucket. Instead of baleen plates, it had ivory teeth in its underslung lower jaw, and in its head was a great reservoir of clear amber oil, which solidified to wax when exposed to the air.

The first industry practiced by the New England colonists was the export of beaver pelts and furs to England, but these commodities were quickly exhausted, and given the availability of the easily killed right whales close to their shores, they turned their attention from the forests to the sea. The earliest colonial whaling was practiced in the Indian manner; towers were erected along the shore to enable lookouts to watch for whales, and when one was sighted, the whalers took to the boats. As navigation improved, the whalers began to roam farther offshore, occasionally visiting the rich grounds of Georges Bank, and some vessels even ventured south into the vast oceanic river that would become known as the Gulf Stream. The Yankee whalers also headed north, toward the Gulf of St. Lawrence and the Grand Banks of Newfoundland. By the middle of the 18th century, there were some 50 ships bringing oil and bone to England and returning with such things as iron ore, hemp, cloth, and other necessities for the burgeoning new colony. By 1775, Nantucket had a fleet of 150 whalers, which ranged in size from 90 to 180 tons.

The beginning of the sperm whale fishery in 1712 did not automatically spare the remaining right whales. Although sperm oil was enormously desirable for lubrication and candle making, the need for whalebone had not abated. In the middle of the 18th century, European women of fashion still required tight-laced corsets, so the New England whalers captured whatever whales they could find and processed them accordingly. Scammon tells us that "shore-whaling continued for over fifty years, but eventually it was abandoned, for the same reason that the Spitsbergen and Smeerenburg fisheries were—the scarcity of whales near the coast."

Regardless of the species being hunted, the primary product of the whale fishery was oil. (Earlier, however, the Dutch and English whalers of Spitsbergen and Greenland had concentrated on the whalebone to the extent that they sometimes cut the slabs of baleen from the mouth of the whale and discarded the carcass. Much of the commerce of whaling was determined by fashion; by the amount of whalebone that would

be required to girdle the ladies.) In America, by contrast, there was no court, no royalty, and, in the mid-18th century Quaker colony of Nantucket, very little fancy dress.

As practiced in the Greenland fishery (and every other whaling operation until that time), the blubber of the whale was cut off in strips (a process known as "making off") and packed directly into casks for transport to the home port. Scoresby, writing in 1820, noted that "in the early ages of the fishery [it was] performed on shore; and even so recently as the middle of the last century, it was customary for ships to proceed into a harbor, and there remain so long as this process was going on." By the middle of the 18th century, an innovation that would change the nature of the entire industry had been introduced: iron caldrons set in a brick furnace enabled the whalers to render the oil from the blubber aboard the ship instead of on shore. This method seems to have evolved around the year 1750, but there is no individual whose name is associated with the invention. Although it is not possible to identify the father of the onboard tryworks, there were many mothers, all of whom had "necessity" as part of their names. Among the reasons for its introduction were the unpleasant odors associated with the onshore boiling of the blubber into oil, and the energetic protests of the people who lived downwind of a noisome blubber works. (Even on board ship, blubber stored in casks tended to spoil quickly, and the stench was overpowering to the whalemen.) On the Spitsbergen and Greenland grounds, the cold climate kept the blubber from turning rancid until the ships could get back to a port, but in New England no such natural refrigeration existed, and the heat often "turned" the oil in the blubber before it could be processed. As long as the whales could be caught within sight—or, at most, a couple of days' sail—of shore, the blubber could be casked and stowed, but when the whales became scarcer in the home waters and longer voyages were required, some other method of processing and stowage was called for. Scoresby (who never employed on-board tryworks, even though the idea existed during his whaling days) wrote that it was less efficient to carry home the blubber, since "blubber in bulk, notwithstanding every precaution . . . generally loses much of its oil."

Now that sperm whales were being processed with some regularity, another change was taking place in the whaling industry. Earlier, all whale oil, casked as blubber or tried-out at sea, was considered usable for lighting and lubrication. (It was often referred to as "train oil," from the Dutch *traan* for "tear" or "drop.") It is a true fat and impregnates every part of the whale, from the bones to the muscles, but most importantly it is found in the blubber. The fat of right whales and bowheads (and the occasional humpback, *Megaptera novaeangliae*) provided the whale oil that was used extensively from the 10th century until the middle of the 19th for heating, lighting, manufacturing of soap and cosmetics, and lubrication of machinery.

Because spermaceti (from the head of the whale) is quite different from train oil, its processing and utilization were also different. Up until the middle of the 19th century, candles were the primary source of indoor light. They were usually made out of wax or tallow and emitted a smelly black smoke as they burned. The head of the sperm whale contained the mysterious fluid that could be used to make a better kind of candle. This wax, which the whale maintains in a liquid form during its lifetime, solidifies when exposed to air, and someone realized that it might be employed in the manufacture of candles. From sometime around 1750, it was used to manufacture smokeless, odorless candles, the best candles known before or since.

In addition to the liquid oil contained in the case, the sperm whale produced a spongy material also impregnated with oil, known to the whalemen as the "junk." The liquid oil in the case and the oil that was squeezed from the junk were collectively known as "head matter" and were used in the finest lamps and candles. The process of manufacture was a fairly complicated one. Upon delivery, the sludge-like substance was heated in a large copper vat and the impurities were drawn off. It was left to congeal in casks and was then bagged in woolen sacks to be pressed later in a large screw press. The oil squeezed from the head matter was the highest quality and was used in lamps. Further processing produced lower qualities of sperm oil, used for candles. Sperm oil candles were particularly popular in Africa and the Caribbean, but as articles of colonial manufacture they could not be imported into England. Both types of oil were considered superior to the train oil of the right whale and were priced accordingly. As the market developed for the finer qualities of oil, colonial entrepreneurs appeared. In 1751, one Benjamin Crabb of Rehoboth, Massachusetts, applied to the state house of representatives for a monopoly of the manufacture and sale of sperm oil candles, which was granted.

As the right whales became scarcer, the tempo picked up for the sperm whale fishery. Starbuck has called the period from 1750 to 1784 "the most eventful era to the whale fishery that it has every passed through." New England whale ships were under constant threat of being captured by privateers (the various wars between France and England for control of the North American colonies were going on at this time), and ships that were not commandeered pursued the fishery as far from home as the Grand Banks and the Bahamas. There were also natural disasters attendant upon the nascent whaling industry: ships were lost to storms and occasionally to whales. For reasons of security and increased profitability, the small sloops that had been the mainstay of the fishery were being replaced by larger ships with tryworks aboard; now the whalers could pursue the sperm whale, "the haughty, elusive aristocrat of the high seas." By this time, the method of lowering boats for whales and fastening to them with harpoons attached to the whaleboats had evolved and would remain the dominant practice for another century. It was this method of whaling—and the great sperm whale—that Melville would immortalize in *Moby Dick*. At this time, the fluctuations in the price of whale oil made for a most uneasy market. Good catches would overload the market and depress the price, while in a bad year, the scarcity of the oil would make it dearer.

The failure of the British whaling industry in the early decades of the 19th century left the field wide open to the New Englanders, and they were quick to capitalize on it. When the French and Indian War ended in 1763 and France conceded her claims to Canada, the New England whalers moved in. They sailed from Massachusetts and New York to the Gulf of St. Lawrence and the Strait of Belle Isle, and by 1776 they had discovered the whaling grounds off western Africa (Angola and

Walvis Bay), the Falkland Islands, and the River Plate grounds of the South Atlantic. In many of these regions, the whalers occasionally encountered a southern right whale (*Eubalaena australis*), but the major object of the fishery by this time had become the sperm whale. These explorers in the name of oil were canvasing the world and perfecting their techniques, but instead of flourishing, they fell deeply into debt. The British government, still trying to support its own collapsing whaling industry, placed a duty on all oil and bone carried to England by colonials. Relations were becoming increasingly strained between the Crown and her rambunctious colony; in the years that followed, the infamous Stamp Act would be enacted and repealed; the Townshend Duties ditto, and finally, the Tea Act was passed in 1773, leading to the Boston Tea Party in the same year. (The East India Company, planning to sell its tea directly to America without having to first sell it to British merchants, shipped 1253 chests of tea from London to Boston on four whale ships: *Beaver, Dartmouth, Eleanor,* and *William and Anne.* It was this tea that the rebels, led by John Hancock and Samuel Adams, dumped into Boston Harbor.) The next 2 years saw the first shots fired at Concord Bridge, and for the ensuing decade, most Americans became preoccupied with things other than whaling. (In April 1775, the same time that the "shot heard round the world" was fired, the ship *Amazon,* Captain Uriah Bunker, was discovering the whaling grounds known as the Brazil Banks, some 500 miles east of that country.)

At approximately the same time that British whalers were depositing their cargoes of convicts and finding themselves in the middle of the rich whaling grounds of Australia and New Zealand, Yankee whalers were cruising almost everywhere in search of sperm whales. It was dangerous work, and sometimes the voyages seemed to last forever, but there were those who saw it as pleasurable and even romantic, the epitome of the wholesome life.

II. Life Aboard a Whaler

In retrospect, however, the voyages were often less than romantic and the weather less than benign. There were indeed fresh breezes, tropical sun, and vast herds of cachalots, but there was also the tedium of years of sailing (the record seems to be the 11-year voyage made by the ship *Nile,* out of New London: 1858 to 1869), as well as gales, blizzards, typhoons, hurricanes, mountainous seas, and howling winds. The crew's quarters were stinking holes; their food was cheap, coarse, and maddeningly monotonous; and the work itself was dirty and dangerous. A voyage aboard a New England whaler was not a luxury cruise.

In the 19th century, the hierarchy of officers and men, so important to the successful operation of a whaling vessel, was rigidly observed, and nowhere was the distinction more evident than in their respective living quarters. The captain lived in relative luxury; the ship's officers had smaller cabins; the boat steerers, the cooper, and the steward occupied the steerage, an irregular compartment fitted with plain bunks. The crew was in the forward section just below the main deck, which followed the shape of the ship: it went from a fairly wide cross section to a narrow, cramped, triangular warren, where the ship's timbers formed the walls, and the pounding of the waves formed the ambience. The lower portion of the foremast often kept the occupants of the fo'c'sle company, reducing even further their limited space, and the only light that entered this literal and figurative rat hole came from the hatchway cut in the deck for the purpose of giving access to the ladder that allowed the men to climb in and out of their quarters. When the weather turned foul, the hatch was closed, and there was no light but stubby candles, and no ventilation whatever. The number of men that occupied this wretched space often exceeded 20.

No whaleman was ever paid a wage, except in unusual circumstances. If, for instance, a full ship had to take on additional hands on the way home, their share of the profits would be zero (since they had not participated in the whaling) and they were paid a monthly wage. Ordinarily, each man, from the captain to the cabin boy, received a percentage of the profits—called a lay—at the end of the voyage.

The distribution differed from vessel to vessel—larger ships could carry more oil, and therefore the profits to the crew were likely to be proportionately higher—but while a successful voyage could be better for the captain and the officers, it meant precious little indeed to the foremast hands. (On an unsuccessful voyage, where the profits were low or nonexistent, the crew might receive nothing at all.) The captain might earn 1/8 or 1/10 of the net proceeds, whereas a mate could earn 1/15 and a harpooner 1/90. Ordinary seamen could hope at best for 1/150, and there are instances in the records where a green hand signed aboard for 1/350. What did this mean in terms of actual money? On board the *Addison,* first mate Ebenezer Nickerson, whose lay was 1/18, earned $845. Robert Baxter, the second mate with 1/35, earned $554.83, and a boat steerer named Narcisco Manuel, with 1/90, got $376.56. Compare these figures to those of the crew: John Martin, at 1/175, earned a total of $31.95 and Francis Finley got $92.08. During six consecutive voyages totaling 1128 days at sea from 1845 to 1868, the average lay per voyage on the Salem whaler *James Maury* was $321.21, or about 26 cents a day. This compared unfavorably to wages then being paid to unskilled laborers ashore (an average of 90 cents a day), but landlubbers did not get to visit exotic Pacific islands where they might be eaten by cannibals or risk their lives fighting gigantic whales.

Infrequently, the men were paid in the specie of whaling; i.e., they received casks of oil, which they were then able to sell at the prevailing prices in their port of disembarkation. The cooks often received an added benefit: in addition to their lays, they were permitted to save the grease (known as "slush") from their galleys and sell it to soap makers ashore.

The whaleman's food and bunk space were generously provided without charge, but throughout the voyage he was docked for various items that he had to buy from the ship's stores. Additional items of clothing, tobacco, knives, needles, and even thread were charged to each man's account, and if he required spending money in a port of call, this too was deducted from the final reckoning. This was a period where the master's voice was law, and if a man needed a new shirt of a pair of boots, he could "either pay up or go naked." Although most of the whalemen signed aboard voluntarily, they usually did not know of the dangers and hardships that lay ahead of them, and the "profit sharing" that at the outset sounded so attractive often deterio-

rated into an enforced "risk sharing," which was invariably uncomfortable, inevitably dirty, and frequently dangerous.

Among the more unusual charges assessed to a whaleman was the cost of desertion. If a man jumped ship, his account included the cost of recapturing him, an expense that was obviously nullified if he remained at large. However, there were captains who rewarded the lookouts with bonuses for the sighting of whales. This exercise was glorified in *Moby Dick*, where Ahab nails a gold doubloon to the mainmast and exhorts his crew: "Whosoever of ye raises me a white-headed whale with a wrinkled brow and a crooked jaw; whosoever of ye raises me that white-headed whale, with three holes punctured in his starboard fluke-look ye, whosoever of ye raises me that same white whale, he shall have this gold ounce, my boys!" The "Spanish ounce" that was offered to the crew was a 16-dollar gold piece.

On a 3- or 4-year voyage, a man might earn $100, but the items billed to him often exceeded this amount, so many hands returned to port not only with no spending money, but in debt. The only thing to do to work off this indebtedness was to sign on for another voyage, thus starting the insidious process all over again. If and when they made it back to port, the whalemen were set upon by all sorts of "land sharks," eager to assist them in disposing of their wages by enticing them into taverns, brothels, and other iniquitous dens where they could make up for the pleasures they had been denied for the past several years. In an 1860 issue of *Harper's* magazine, an observer describes the arrival of the whalemen in New Bedford:

> A cart rattles by, loaded with recently discharged whalemen—a motley and a savage-looking crew, unkempt and unshaven, capped with the head-gear of various foreign climes and peoples—under the friendly guidance of a land shark, hastening to the sign of the "Mermaid," the "Whale," or the "Grampus," where, in drunkenness and debauchery, they may soonest get rid of their hard-earned wages, and in the shortest space of time arrive at that condition of poverty and disgust of shore life that must induce them to ship for another four years' cruise.

The system of wages aboard a whaler was obviously not conducive to enthusiasm or hard work. In response to the brutal discipline often administered by the captain, there was bound to be apathy, indifference, and suspicion on the part of the foremast hands. There was also a profound class distinction between the officers and the men. Despite the abuses, hardships, and low earnings that characterized the industry, however, the labor supply was somehow adequate to meet its needs. As Hohman has written, "The steady stream of men pouring into the forecastles proved sufficient to counteract the continuous labor leakage caused by death, illness, incapacity, discharge and desertion." It was possible (although uncommon) for a dedicated seaman to work his way up through the ranks, and there are instances where a green hand, or even a cabin boy, raised his lay from 1/150 to 1/15, and after perhaps 20 years at sea (in 4- or 5-year increments), a man might command a whaling vessel.

The *Benjamin Tucker*, a New Bedford whaler, brought back 73,707 gallons of whale oil, 5348 gallons of sperm oil, and 30,012 pounds of whalebone in a voyage that ended in 1851. At the prevailing prices—43 cents a gallon for whale oil, $1.25 a gallon for sperm oil, and 31 cents a pound for bone—the gross value of this cargo was $47,682.73. From this, $2362.73 was variously deducted, leaving a net of $45,320 to be distributed. Before the profits were divided, however, the owners took a substantial percentage off the top to compensate for their initial outlay and also because these flinty New Englanders were not in the business for the thrill of the chase. In general, the owners took between 60 and 70% of the profits. On the 1805–1807 cruise of the *Lion*, the various oils yielded a total of $37,661.02. Of this, $24,252.74 went directly to the owners, leaving $13,045.53 to be divided among the captain and the crew for 2 years of work.

During its heyday, New Bedford was the richest municipality per capita in America, and Melville described it as "perhaps the dearest place to live in all New England . . . nowhere in America will you find more patrician-like houses, [or] parks and gardens more opulent."

Of course, profits from the whaling industry were not restricted to the owners. They had to repair, refit, and reprovision their ships, which provided work and income for the shipwrights, chandlers, coopers, rope makers, carpenters, and blacksmiths, and ready markets for the farmers and greengrocers. The entire township of New Bedford benefited from the outfitting and victualing of the armada of ships that annually departed her wharves, loaded with food, clothing, and supplies, most of which were bought from local merchants.

The captain had his own cabin, with a proper bunk, a washstand, a table, and perhaps even a sofa and some extra chairs. The captain's quarters of the whale ship *Florida* "opened off the after cabin on the starboard side and extended nearly to the end of the forward cabin. A small room and a toilet room were aft of the stateroom. A large swinging bed was in the captain's cabin instead of the usual fixed berth." The gimballed bed was a special innovation designed by Captain Thomas Williams because he was planning to bring Mrs. Williams along.

Occasionally a captain took his wife and, even more infrequently, he took his entire family. Captain Williams, of the ship *Florida* out of New Bedford, was accompanied by his wife for a voyage that lasted from September 1858 to October 1861. During the voyage, Eliza Azelia Williams gave birth to two children, who spent the first years of their lives at sea. She also kept a detailed journal of her adventures, which allows us a most unusual perspective of life aboard a whale ship. The voyage commenced on September 7, 1858, in New Bedford, and on January 12 of the next year, Mrs. Williams gave birth to a baby boy, whom they named William. (William's arrival might help explain her seasickness early in the voyage, when she wrote, "it remains rugged and I remain Sea sick. I call it a gale, but my Husband laughs at me and tells me I have not seen a gale yet. If this is not one I know I do not want to see one.") On August 5, 1859, off the rugged coasts of Sakhalin in the Okhotsk Sea, the *Florida* spoke the *Eliza F. Mason*, and Mrs. Williams visited another "lady ship," where the captain had brought his wife and child, "a Lady Companion, and a little Girl that they brought from the Bay of Islands, New Zealand." On February 27, 1860, Mrs. Williams wrote, "We have had an addition to the Florida's Crew in the form of our little daughter. . . ."

It was United States maritime law that a logbook be maintained by the mate or the first officer. (The term "log book" orig-

inated with the practice of casting a log overboard affixed to the ship by a knotted line. The speed at which the line played out—measured in knots—determined the speed of the ship, and the daily records were originally kept in a book reserved for that purpose. Later, the term "logbook" was used to designate the book used for the keeping of all the ship's records.) For the most part, logbooks and journals were kept by the masters. Although rarely educated in the classical sense, most of these men could read and write passably well, and their records have given us an enduring picture of life aboard a whale ship. Even though the maintenance of a logbook was mandatory, it obviously served the whalers particularly well, as the appearance of whales at a known latitude and longitude in one season might enable the whalers to predict their reappearance at the same location the following year, thereby avoiding aimless wandering.

The more mundane entries consisted of the ship's position, the number of whales caught, and illness and injury aboard ship, but additional dramatic possibilities were vast. Whaling historian Stuart Sherman, in his introduction to the catalogue of the logbook collection of Paul Nicholson, listed "castaways, mutinies, desertions, floggings, women stowaways, drunkenness, illicit shore leave experience, scurvy, fever, collisions, fire at sea, stove boats, drownings, hurricanes, earthquakes, tidal waves, shipwrecks, ships struck by lightning, men falling from the masthead, hostile natives, barratry, brutal skippers, escape from Confederate raiders, hard luck voyages and ships crushed by ice." That is not to say that all logbooks read like *Moby Dick;* dramatic events occurred infrequently, and most of the daily entries—when the ship was not engaged in killing whales—consisted of a remark on the wind direction, the location, and whatever else the keeper of the logbook deemed pertinent.

It is not surprising that few of the foremast hands kept records; their quarters were not conducive to the literary life, and besides, many of them could not write. Francis Olmstead could. Of the literary aspirations of his fo'c'sle companions, he wrote:

> The forecastle of the *North America* is much larger than those of most ships of her tonnage, and is scrubbed out regularly every morning. There is a table and a lamp, so that the men have conveniences for reading and writing if they choose to avail themselves of them; and many of them are practicing writing every day or learning how to write. . . . When not otherwise occupied, they draw books from the library in the cabin and read; or if they do not know how, get someone to teach them. We have a good library on board, consisting of about two hundred volumes. . . .

J. Ross Browne, a journalist who shipped aboard the New Bedford whaler *Bruce* in 1842, kept a journal of his experiences that was published, with major revisions, as *Etchings of a Whaling Cruise* in 1846. Browne wanted to do for whaling what Richard Henry Dana had done for merchant sailing in 1840, i.e., exaggerate the problems so that necessary changes would be implemented. Although his account may contain a certain amount of propaganda in the form of negative commentary, he was aboard a whaler for more than a year, and because he is regarded as a reporter and not a writer of fiction, much of the material contained in his book can be taken as fact. Here is Browne's description of the place in which he lived:

> The forecastle was black and slimy with filth, very small and hot as an oven. It was filled with a compound of foul air, smoke, sea-chests, soap-kegs, greasy pans, tainted meat, Portuguese ruffians and sea-sick Americans. . . . In wet weather, when most of the hands were below, cursing, smoking, singing and spinning yarns, it was a perfect Bedlam. Think of three or four Portuguese, a couple of Irishmen, and five or six tough Americans, in a hole about sixteen feet wide, and as many perhaps, from the bulk-heads to the fore-peak; so low that a full-grown person could not stand upright in it, and so wedged with rubbish as to leave scarcely room for a foothold. It contained twelve small berths, and with fourteen chests in the little area around the ladder, seldom admitted of being cleaned. In warm weather it was insufferably close. It would seem like an exaggeration to say, that I have seen Kentucky pig-sties not half so filthy, and in every respect preferable to this miserable hole; such, however, is the fact.

Rats were more numerous on whale ships than on any other vessels, probably because of the profusion of blood and oil that soaked the decks, despite the regular scrubbings. They were more than any ship's cat could cope with, and then as now, there was nothing that could cope with cockroaches. They were endemic aboard the whalers, and for many seamen, the roaches were a more predominant aspect of a whaling voyage than whales. Francis Olmstead wrote that they made "a noise like a flush of quails among the dry leaves of the forest . . . they are extremely voracious, and destroy almost everything they can find: their teeth are so sharp, the sailors say, that they will eat the edge off a razor."

In *Nimrod of the Sea,* William Davis describes roaches as serving a useful purpose: "His chief recommendation in his insane pursuit of the flea . . .," but then goes on, "it is a horrible experience to awaken at night, in a climate so warm that a finger-ring is the utmost cover you can endure, with the wretched sensation of an army of cockroaches climbing up both legs in search of some Spanish unfortunate! It reminds me of how many times I have placed my tin plate in the overhead nettings of the forecastle, with a liberal lump of duff reserved from dinner, and on taking it down at supper, have found it scraped clean by the same guerrillas. They leave no food alone, and have a nasty odor, which hot water will scarcely remove. But one becomes philosophical at sea in matters of food."

The crew's rations aboard a whale ship ranged from bad to disgusting, but, Browne says, "a good appetite makes almost any kind of food palatable." He describes the usual fare on board the *Bruce* (which he has, for culinary and other reasons, named the *Styx*): "I had seen the time when my fastidious taste revolted at a piece of good wholesome bread without butter, and many a time I had lost a meal by discovering a fly on my plate. I was now glad enough to get a hard biscuit and a piece of greasy pork; and it did not at all affect my appetite to see the mangled bodies of divers well-fed cockroaches in my molasses; indeed, I sometimes thought they gave it a rich flavor." Fresh vegetables were taken on at the outset of a voyage and were often picked up when the vessel put in for provisions, but unless they were used quickly, they rotted. (By Browne's time, the causes of scurvy were known, but if the vegetables were used

up and the ship was cruising somewhere off the Aleutian Islands, there was not much anyone could do to prevent the dread disease.) Because of their inability to store much water—and to prevent it from spoiling—the whalers hardly ever drank it. (Scammon tells the story of one captain, who, to preserve the dwindling water supply, had the drinking cup hung from the royal-masthead, requiring any man who wanted a drink to climb all the way up after the cup.) They drank "longlick," a mixture of tea, coffee, and molasses, and if the cook was imaginative, he prepared something known as "lobscouse" (or simply "scouse"), which was a hash made of hard biscuits that had been soaked in the greasy water left over after boiling the salted meat. The mainstay of the whaler's diet was salted meat, which was supposed to be pork or beef, but was occasionally horse. In *Omoo*, Melville described the meat on board a whaleship:

> When opened, the barrels of pork looked as if preserved in iron rust, and diffused an odor like a stale ragout. The beef was worse yet; a mahogany-colored fibrous substance, so tough and tasteless, that I almost believed the cook's story of a horse's hoof with the shoe on having been fished up out of the pickle of one of the casks.

Because the everyday food was so often inedible (Nordhoff describes the duff made by a certain cook as "that potent breeder of heartburns, indigestion, and dyspepsia . . . the very acme of indigestibility," and Ben-Ezra Ely wrote, ". . . no swine that gleans the gutters ever subsisted on viler meat and bread than did our crew"), the opportunity to eat something fresh was a blessing. The cook prepared seabirds, whatever fish they could catch, turtles, dolphins (off the African coast, Nordhoff describes the harpooning and subsequent eating of a hippopotamus), and because they were engaged in the capture of 50- or 60-ton mammals whose carcasses they would otherwise leave for the sharks, they often ate the meat of the whales. On the eating of various parts of the whale, usually during the trying-out, Browne writes:

> About the middle of the watch they get up the bread kid [a kid was a wooden tub] and, after dipping a few biscuits in salt water, heave them into a strainer, and boil them in oil. It is difficult to form any idea of the luxury of this delicious mode of cooking on a long nightwatch. Sometimes, when on friendly terms with the steward, they make fritters of the brains of the whale mixed with flour and cook them in the oil. These are considered a most sumptuous delicacy. Certain portions of the whale's flesh are also eaten with relish, though, to my thinking not a very great luxury being coarse and strong. . . .

It was a different world above decks. On December 28, 1856, the crew of the New Bedford whaler *Addison* caught a porpoise, and Mary Chipman Lawrence (the captain's wife) wrote in her journal, "The meat looks very much like beef. The oil is contained in the skin, which they will boil out tomorrow. Had some of the meat fried for dinner and some made into sausage cakes for supper. They are as nice as pork sausages." If a further demonstration of the disparity between the fare of the men and that of the officers is required, here is Mrs. Lawrence's description of Christmas dinner for that same year: "roast chickens, stuffed potatoes, turnips, onions, stewed cranberries, pickled beets and cucumbers, and a plum duff. For tea I had a tin of preserved grape opened and cut a loaf of fruitcake."

Unlike their British counterparts, American whalers rarely carried any sort of medical man. It commonly fell to the captain to cope with whatever illness or accident befell his crew, and given the master's experience, it was considerably safer to remain healthy. For internal maladies, whale ships were often equipped with medicine chests, which contained various potions and a manual for their dispensation. (Stories were told of masters who, having run out of medicament Number 12, simply administered equal amounts of Numbers 5 and 7.)

Physical injuries were not uncommon, considering the number of sharp-edged tools, whistling whale lines, and hostile natives, not to mention shipboard arguments between men who were almost always armed with knives. Here again, the master served in the role of surgeon, with the same amount of training as he had as apothecary. In *Nimrod of the Sea*, W. M. Davis tells the gory tale of a whaleman who was yanked from his boat by a kinked line and dragged some 125 fathoms from the boat. When he was finally picked up, "it was found that a portion of the hand, including four fingers, had been torn away, and the foot sawed through at the ankle, leaving only the great tendon and the heel suspended to the lacerated stump." Equipped with "his carving knife, carpenter's saw and a fish-hook," the captain "amputated the leg and dressed the hand as best he could."

III. Whale Ships and Whaleboats

As whaling voyages increased in distance and duration, it became expedient to enlarge the ships. In the early days of the fishery (around 1820), the ships averaged around 280 tons burthen, but within two decades, 400-ton vessels were not uncommon. The move toward bigger whale ships contributed to the decline of Nantucket whaling because there was a prominent sandbar across the harbor, and only the smaller, shallower-draft ships could enter. New Bedford, with its excellent harbor facilities, took up the slack.

All whaling vessels were ships—as opposed to *boats*, which were the smaller vessels that the whalers rowed after their quarry. The literature is replete, however, with references to ships, brigs, brigantines, barks, barkentines, and schooners. These differentiations have to do with the rigging of the masts and not with the number of masts, although a three-masted, square-rigged vessel was always known as a ship. If the aftermost mast was rigged fore and aft, with the sail slung between a gaff and a boom, the vessel was known as a *bark*, the commonest plan, because fewer hands were required to handle the sails, and thus there were more men available for the boats. There were further variations, including the *brig*, where the upper courses of the aftermost mast were rigged with square sails, but there was also a fore-and-aft sail known as a "spanker." A *barkentine* was square-rigged only on the foremast, the rest fore and aft, and a *brigantine* had only two masts, the foremast square-rigged and the mainmast fore and aft. A *schooner* had two or more masts, rigged fore and aft.

Whale ships differed from merchantmen of the time in that they usually carried less sail. More canvas meant more men

aloft, and the whalers needed as many hands as possible for the boats. One further characteristic of the whaler was the presence of masthead hoops, in which the lookouts stood during the daylight hours to watch for whales.

Square-rigged ships, which gave their name to an era of sailing, ran powerfully before the wind, but were not particularly handy in head- or crosswinds. The whalers did not have to perform any smart sailing maneuvers, nor did they have to sail with great speed. All they had to do was get from one location to another and then lower the boats after the whales. Because of the determined, plodding nature of their craft, the masters rarely sailed at night, preferring instead to furl their sails and wait until dawn before continuing.

It was during the heyday of New England whaling, from 1830 to 1860, that the fabulous clipper ships reached the zenith of sailing-ship design, with their graceful lines, sharply raked bows, and opulence of canvas. In marked contrast to these ocean-going grayhounds, the whalers were sturdy, bluff-bowed, flat-bottomed sailers, designed more for durability and storage than for speed. (The *Lagoda* sailed for 50 years, and the all-time record holder, the *Charles W. Morgan*, sailed for more than 80 years and earned over a million dollars for her owners. The *Lagoda* was copied at half-scale for the New Bedford Whaling Museum, and the *Morgan*, the last of her kind, is now the proud centerpiece of Mystic Seaport in Connecticut.)

A typical whaler was 100 to 150 feet long, and especially broad in the beam to accommodate the fixtures of whaling: heavy brick tryworks on deck, iron caldrons, cooling tanks, davits for the boats, and, of course, the space required to perform the trying-out of the whale. Ordinary seamen, whose voyages did not take 4 or 5 years, belittled the whale ships as "built by the mile and cut off in lengths as you want 'em." They were usually painted black and had mock gun ports painted along the sides, supposedly as a deterrent to pirates or hostile savages.

The naval historian Albert Cook Church wrote: "Whaleships differed materially from any other type of merchant ship or clipper in model and equipment, and in fact, both sides of a whaleship differed from each other above the waterline." The larger ships were equipped with four boats: one on the starboard quarter and three on the port (also known as the "larboard") side. This allowed the cutting stages, which were always on the starboard, to be lowered without interference from davits.

When a whale or a group of whales was sighted, the lookout shouted "She blows!" or "Blows!" and when the captain had ascertained "where away," the boats were lowered and the chase began. All the boats might be lowered, depending on the number of whales sighted. If only a single whale was seen, the captain might designate one boat to chase it. The starboard boat was reserved for the captain (or the fourth mate, if the captain chose to stay aboard ship during the hunt); the larboard, waist, and bow boats were for the first, second, and third mates, respectively. Each boat contained a regular crew, consisting of five oarsmen and a boat steerer/harpooner. Whoever was in command of the whaleboat pulled the steering oar and gave the orders. The boats were double enders; in case they got turned around in the frenzy of the hunt, they would be able to maneuver, and they were among the most graceful and utilitarian boats ever designed.

All the requisite equipment would be stowed carefully aboard the whaleboats, from the line, which was carefully coiled in a tub so it could be let out rapidly, to the knife that might be required to cut it if a man got his leg entangled. In addition to the six adult men who would be required to man the boat, Scammon lists the contents of a fully equipped whaleboat:

> One mast and one yard, one to three sails, five pulling oars, one steering oar, five paddles, three rowlocks, five harpoons, one or two line-tubs, three hand lances, three shortwarps, one boat-spade, three lance-warps, one boat-warp, one boat-hatchet, two boat knives, one boat-waif, one boatcompass, one boat-hook, one drag, one grapnel, one boat-anchor, one sweeping-line, lead, buoy, etc., one boat-keg, one boat-bucket, one piggin, one lantern-keg (containing flint, steel, box of tinder, lantern, candles, bread, tobacco, and pipes), one boat-crotch, one tub-oar crotch, half a dozen chock pins, a roll of canvas, a paper of tacks, two nippers, to which may be added a bomb-gun and four bomb-lances, in all, forty-eight articles, and at least eighty-two pieces.

IV. Killing and Processing the Whale

The lowering of the boats took place as the ship was underway; the captain did not come about for the comfort or convenience of his crews. Often in high seas, the graceful whaleboats took off after the whales with the men facing the stern; the boat steerer was the only man who could see the whales. When they had come within range, the harpooner threw the harpoon. It consisted of a wooden shaft, some 6 feet in length, with a forged iron head. The earliest harpoons had simple fluted arrowhead-shaped heads, but as the fishery developed, more sophisticated designs were introduced. While the two-flued iron pierced the blubber effectively, its razor edges would occasionally pull out as smoothly as they went in. This led to the introduction of the single-flued iron, which held much better. Harpooners and blacksmiths had plenty of time, on board the whalers and in port, to work on harpoon design, and all sorts of elaborate heads with toggles, barbs, and swivels were tried. The most successful of these designs was the double-barbed "Temple" iron, invented in 1848 by a New Bedford blacksmith named Lewis Temple. A graceful, practical device, the Temple iron consisted of a pointed head that was held in the forward position by a wooden shear pin that broke off when withdrawal forces were applied. This rotated the head 90° in the flesh of the whale, forming a T-shaped device that would not pull out because the flattened surfaces were pulling against the meat or blubber. The iron was fastened to the shaft of the harpoon by a line that was bent to the heavy manila line. The line, which Melville calls the "magical, sometimes horrible whale-line," was originally fashioned of hemp, but was later superseded by manila rope, which was stronger and more elastic. "Hemp is a dusky, dark fellow," Melville wrote, "a sort of Indian, but Manilla is as a golden haired Circassian to behold."

Even though tradition demanded that the harpoon and the lance be thrown separately, some creative whalemen tried to design an iron that would fasten to and kill the whale simultaneously. A Scottish toxicologist named Robert Christson invented a poison-headed harpoon, equipped with glass cylinders

containing prussic acid, one drop of which is lethal enough to kill a man. There is no evidence that prussic acid harpoons were used in the American fishery, but they were carried on some vessels. The likelihood is that the American harpooners felt that they had enough problems killing the whale without worrying about killing themselves.

If the iron was well placed—the ideal spot was in the flank, forward of the hump—the boat was fast to the whale, and the injured animal took off. Sometimes the whale sounded, taking out the line at such speed that the line smoked as it ran out, and the loggerhead had to be doused with water to keep it from bursting into flames. More often the whale swam at the surface, towing the boat through the waves at a violent clip. Sperm whales are prodigious divers, and no boat could hold enough line for a dive that could be measured in miles. If the whale sounded, another 200-fathom line might be bent to the first and then another. Eventually, the wounded whale had to surface to breathe.

The lance, also known as the "killing iron," was plunged into the "life" of the whale, a vital artery, the lungs, or the heart. The killing iron consisted of a wooden shaft like that of the harpoon, with a scalpel-sharp head. It was not thrown, but rather stabbed repeatedly into the body of the whale. Melville describes the death throes of a whale:

> The red tide now poured from all sides of the monster like brooks down a hill. His tormented body rolled not in brine but in blood, Which bubbled and seethed in furlongs behind in their wake. The slanting sun playing upon this crimson pond in the sea sent back its reflection into every face, so that they all glowed to each other like red men. . . . Stubb slowly churned his long sharp lance into the fish and kept it there, carefully churning and churning, as if cautiously seeking to find some gold watch that the whale might have swallowed, and which he was fearful of breaking ere he could hook it out.

The victory did not always go to the whalers. Sperm whales are immensely powerful creatures and do not take kindly to being stabbed with spears. The most frequent problem occurred when the whale took it into its 20-pound brain to retaliate. A 30-foot whaleboat was no match for an enraged, wounded, 60-ton whale, and the harpooned animal might rise up from the depths and grab the boat in its massive jaws, splintering it into so many matchsticks. Both ends of a wounded whale are lethal; the triangular flukes, which might measure 20 feet across, could function as a formidable weapon, crashing down upon the whaleboat and dumping the men into the sea. Other perils faced the whalemen, where the whistling line might take a turn around a leg or an arm, surgically severing it, or yanking the man into the water. Even if the boat was not destroyed, it might be upended and its occupants dumped into the ocean. Many of them could not swim, so such a plunge often spelled death.

More often than not, however, the world's deadliest predator won the battle and then faced the problem of bringing whale and ship together. If the conquering whaleboat was downwind of the ship, it was a relatively simple matter to sail the ship to the carcass, but if less propitious conditions prevailed, the exhausted whalemen might have to tow the whale back to the ship, often for miles. Then, after an exhausting chase and a laborious haul with a 50-ton deadweight in tow, the real work began. What had been a free-swimming, powerful sea mammal was effectively reduced to a disparate assortment of its parts, the reduction accomplished by literally tearing it apart.

As in virtually every other aspect of New England whaling, the cutting-in process was described better by Melville than anybody else. (In the Yankee whale fishery, the process of removing the whale from his outer integuments was known as "cutting-in," and the rendering of the blubber into oil was known as "trying-out." In the English fishery, these operations were known respectively as "flensing" and "making off.") In *Moby Dick* there is one chapter devoted to the actual process and several more to the by-products, including the "blanket," the "funeral," and the "sphynx"—the last referring to the head of the whale after the body and blubber have been separated from it.

The whale was made fast to the ship by lashing heavy chains through its head and around its flukes. The first part of the whale to be brought aboard was the lower jaw, ripped from the head and laid aside to be dealt with later. Then the whale was decapitated, and if it was a small one, the head was brought aboard. The head of a large whale, often one-third of its 60-foot, 60-ton body, could not be brought on deck (Melville wrote that "even by the immense tackles of the whaler, this were as vain a thing as to attempt weighing a Dutch barn in jeweller's scales") and had to be processed in the water. The "head matter" was saved for last, however, because the carcass of the whale alongside the ship was threatening to the ship by its weight, and the longer it remained unprocessed, the longer the sharks could wreak havoc on the very outer layer of blubber that was of so much interest to the whalers.

By the use of a complicated series of tackles—described by Melville as "ponderous things comprising a cluster of blocks generally painted green, and which no single man can possibly lift—the cutting stages were lowered, and the process of removing the blubber commenced. Sitting or standing on the lowered cutting stages, men with razor-sharp cutting spades began to slice into the whale's rubbery outer covering. A massive iron hook was inserted in the first piece to come off, which was hoisted high into the air while the men on the scaffold sliced the blubber. The whale was rotated in the water, and its blubber "stripped off from the body precisely as an orange is sometimes stripped by spiralizing it." The power for this peeling and dismemberment came from the strong backs of the whalemen, who turned the windlass located forward of the foremast.

As the thick spiral of blubber was peeled from the whale, it was cut into sections approximately 15 feet long and a ton in weight (the "blanket pieces"). These were dropped through a hatch into the blubber room, where they were stored until the carcass of the whale was completely stripped. (With the removal of the blubber and the head, the remainder of the carcass was left for the sharks.) Workers in the dark, bloody blubber room further reduced the blanket pieces to smaller, more manageable "horse pieces," which were then sliced into "Bible leaves," with cuts almost to the skin, making them resemble the

splayed pages of a thick-leaved book. (It was believed that the opening of the blubber into "pages" made the oil more accessible.) The Bible leaves were then forked back up through the forehatch to the men who would place them in the trypots.

Although the trypot fires were usually started with wood, the unmelted skin of the whale made a wonderful fuel, and the whale was therefore cooked in a fire of its own kindling. As the oil was separated from the blubber, it was carefully ladled into a copper cooling tank, where it rested before being casked. Aside from the obvious danger of a fire spreading, the process was—like almost every aspect of whaling—hard, messy, and dirty. Oil and blood covered the decks and the people, and the smell was often intolerable. J. Ross Browne called the trying-out process "the most stirring part of the whaling business, and certainly the most disagreeable." He described the nighttime scene aboard the *Styx:*

> Dense clouds of lurid smoke are curling up to the tops, shrouding the rigging from the view. The oil is hissing in the trypots. Half a dozen of the crew are sitting on the windlass, their rough, weather-beaten faces shining in the red glare of the fires, all clothed in greasy duck, and forming about as savage a looking group as ever was sketched by the pencil of Salvator Rosa. The cooper and one of the mates are raking up the fires with long bars of wood or iron. The decks, bulwarks, railing, try-works, and windlass are covered with oil and slime of black-skin, glistering with the red glare of the try-works. Slowly and doggedly the vessel is pitching her way through the rough seas, looking as if enveloped in flames.

At the end of this description, he wrote, "Of the unpleasant effects of the smoke I scarcely know how any idea can be formed, unless the curious inquirer choose to hold his nose over the smoking wick of a sperm oil lamp, and fancy the disagreeable experiment magnified a hundred thousand fold. Such is the romance of life in the whale fishery."

One of the least romantic aspects of the whale fishery was the prospect of fire. Oil-soaked wooden ships upon whose decks fires are being encouraged do not lend themselves to a feeling of security. Care was taken to avoid conflagrations—water was pumped over the decks to keep the planks wet and cool—but occasionally the sails or rigging were ignited by flying sparks, and sometimes the ships burned to the waterline.

When the oil had cooled, it was ladled into the casks that had been assembled by the cooper. Each barrel held 302 gallons, and the figures for the fishery were almost always recorded in barrels. Starbuck's 1878 *History of the Whale Fishery,* which contains the records of every American whaling ship, from every American whaling port, "from its earliest inception to 1876" (insofar as these records were known), lists the result of every whaling voyage in sperm oil (barrels), whale oil (barrels), and whalebone (pounds).

A large female sperm whale might yield 35 barrels of oil, while the largest bulls gave up 75 to 90. As with the sometimes questionable lengths of large bulls, where there were reports of 90 footers (Clifford Ashley writes, "If these whalemen's records are accurate, it would appear that the hundred-foot Sperm Whale is not an impossibility"), the yield of these giants was the subject of occasional exaggeration. Because the reports were invariably made by men whose reputation would be enhanced by overstating the yield of individual whales, many of the whales in the 100- to 150-barrel range must be questioned.[1]

The amount of oil that could be taken and stored was enormous, but it did not necessarily reflect the success of a voyage. The profits of a voyage could only be calculated when the ship reached port and sold the oil and bone at the prevailing prices. A 31-gallon cask was about 5 feet high and 4 feet in diameter at its bulging middle (Fig. 1). On her maiden whaling voyage, which lasted from October 1841 to September 1843, the *Lagoda* brought home 600 barrels of sperm oil, 2700 barrels of whale oil, and 17,000 pounds of baleen. ("Sperm oil" was the stuff that was ladled out of the whale's "case" and was of a finer quality than "whale oil," which was rendered out of the blubber. Although they were not averse to taking an occasional right whale or humpback, most of the whales hunted by the Yankees were sperm whales.) The *Lagoda* was 108 feet long, with a beam of 27 feet. Hunting concluded when there was no more room for the storage of oil, but the whalers sometimes put into port, off-loaded some of their greasy cargo, and set out again for the whaling grounds. Some of these sweaty, iron-bound vats were probably stored in the blubber room, but most were stored in the hold.

It was the mysterious "head matter" of the sperm whale that made it the primary object of this globe-girdling enterprise. Other whales were encased in blubber, and some of them had the long "finnes" that could be converted into milady's bodices. The spermaceti, however, was the *ne plus ultra* of this business, the pot of liquid gold that attracted the whalers to the Azores and the Galapagos, to Zanzibar and the Japan Grounds, to Kamchatka and the Okhotsk Sea. The stuff is as poorly understood today as it was when some early beachcomber presumed that this vast reservoir in the whale's nose was its seminal fluid. Whatever its purpose to the whale (and it certainly is not its seminal fluid), the amber wax that hardened white as it was exposed to air was worth risking life and limb—and sometimes boat and ship—to the whaler. Kept free from contamination by other oils, sperm oil was worth from three to five times as much as whale oil. In *Nimrod of the Sea,* W. M. Davis records a whale that yielded 27 barrels of spermaceti from the case, and Clifford Ashley's research indicates that the largest bulls gave up something on the order of 30 barrels. At 31.5 gallons per barrel, that works out to 945 gallons of the mysterious liquid wax in the nose of a single whale.

To extract the spermaceti from the head, a much more direct method was employed than the multistep process of turn-

[1] If only the whalers' stories remained, we would have no way of verifying the size of the largest whales. There is something that they leave behind, however, and Ashley proposes a novel argument for the existence of gigantic bull sperm whales: he examines a particularly large pair of teeth, over 11 inches long, and suggests that "in the days before the Sperm Whale herds were depleted, there must have been exceptional whales, either larger or older than are found today." Mitchell (1983) finds this argument "well taken, but not conclusive," but a look at these teeth, which are on display in the New Bedford Whaling Museum, certainly gives one cause to wonder.

Figure 1 *Casks of oil line the New Bedford wharf. Photo by Old Dartmouth Historical Society—New Bedford Whaling Museum.*

ing blubber into oil. Because the spermaceti already *was* oil, the whalers only had to remove it from the whale and cask it. A hole was cut in the outer fabric of the whale and a man lowered a bucket into it on a long pole and then turned it over to another man on deck who would empty the bucket into a waiting tub—or as Melville put it, "Tashtego downward guides the bucket into the Tun, till it entirely disappears; then giving the word to the seamen at the whip, up comes the bucket again, all bubbling like a dairy-maid's pail of new milk."

When the oil had all been casked and the casks stowed, the decks were scrubbed down with lye, which had been leached from the cinders and ashes of the tryworks, and the oily, smoky clothes of the whalemen were also scrubbed down, but the pernicious odor of smoked blubber could never really be removed, and until they could exchange their work clothes for new garments, the whalemen usually smelled like disused tryworks.

V. Bowhead Whaling

The gigantic nose of the sperm whale contains an enormous quantity of valuable oil, which was the primary object of the sperm whalers. Bowheads (*Balaena mysticetus*) are fatter than sperm whales, and their blubber thicker, but it was not so much for the blubber that the bowheads were hunted: their huge, arched mouths contained the longest baleen plates of any whale and it was this that the whalers were after. It was used for the manufacture of skirt hoops, corset stays, horsewhips, and dozens of other necessities of 19th century America.

In July 1848, Captain Thomas Welcome Roys, a sperm whaler out of Sag Harbor (New York), sailed through Bering Strait, a thousand miles farther north than any whale ship had ever gone in the Pacific, and came upon a thriving population of bowheads that had previously been known only to Eskimos. His crews took 11 bowheads in only 35 days during that eventful summer and sailed for home with 1800 barrels of oil, an accomplishment that normally took two or more seasons. According to John Bockstoce, the historian of western Arctic whaling, "Roys's cruise was not only the most important whaling discovery of the nineteenth century, it was also one of the most important events in the history of the Pacific. . . . More than 2,700 whaling voyages were made into Arctic waters at a cost of more than 150 whaleships lost and the near extinction of the bowhead whale, as Roys's whales came to be called." Arctic bowhead whalers also changed the way in which whales were hunted; instead of hand-thrown harpoons, they introduced the efficiency of artillery, shooting at the whales first with shoulder guns, and later killing them with bomb lances.

Many New England whaleships had been captured or burned by the Confederate raider *Shenandoah* in 1865, and to revive the flagging industry, 39 ships sailed to the Arctic in

April 1871. By August, 32 of them were trapped in the ice off Point Barrow, Alaska. The 7 remaining ships took on 1129 men and brought them back to Honolulu, signaling the beginning of the end of Arctic bowhead whaling.

VI. The "Romance" of Whaling

In the 19th century, when so much of the world was still unexplored, whalemen faced even greater hazards than an occasional angry whale. The United States exploring expedition under Wilkes had visited many of the island groups in the Central Pacific and found that some of the stories of hostile savages, often cannibals, were true. The Fiji Islands were known—more or less accurately—as The Cannibal Isles, and whenever possible the whalers avoided them. In 1835, the whaler *Awashonks*, out of Falmouth, was attacked by the natives of Namarik in the Marshall Islands, and the captain, the first and second mates, and four crew members were killed before an enterprising whaleman dynamited the deck where the would-be conquerors were standing, and the ship was retaken. The *Syren* was recaptured from Palauan natives only after a box of tacks was scattered on deck, driving the barefoot raiders howling overboard.

The need for fresh vegetables and water often outweighed the threat of being attacked, and even though many of the captains knew or had heard stories of cannibalism and "cutoffs" (a whaleship captured by natives and its crew massacred), they could not resist the temptations of cheap provisioning. Whale ships hardly ever carried money; the very same "slop chest" that provided the foremast hands with their replacement items of clothing also served as a trading bank. "Recruiting ship" was the term used to describe the acquisition of provisions, and the captain would trade cotton cloth, powder, tobacco, knives and beads for fresh food and water. It was sometimes too much for the parsimonious New Englanders to resist: for a couple of pounds of tobacco or some rusted iron hoops, they could trade for pigs, coconuts, water, wood, and women.

The quality of life aboard a whaler was hardly luxurious, but it was often better than life on the farm. Indeed, many whalemen deserted on the islands, not because they were unduly harassed or flogged, but because life on a lush, green island, with free food and even freer women, was an economic and sociological step upward. By the middle of the 19th century, there may have been as many as 3000 deserters from whale ships scattered throughout the coral archipelagoes of Micronesia and Polynesia.

Hawaii, Tahiti, and the Marquesas are picturebook "South Sea Islands," with tall volcanic mountains, tumbling waterfalls, broad white beaches, and swaying palms. When Herman Melville jumped ship in the Marquesas and subsequently described his experiences in *Typee*, he was responsible for many misinterpretations of life on a tropical island. Not all island groups boasted plentiful paw-paws and willing wahines. Many of these tiny specks in the Pacific were mercilessly unforgiving coral atolls; low rings of sand that had only recently risen out of the Pacific. All along the equator in the Pacific—the grounds known as "On the Line"—sperm whales occurred in some profusion. While the vicinity of the Gilbert Islands (then known as the Kingsmill Group) was a good place to kill sperm whales, it was almost as dangerous for the whalers as it was for the whales. The Gilbertese natives were a particularly aggressive and warlike people, but there were also many beachcombers who had been stranded on these islands, men who were eager to lead the natives in attacks on visiting whalers.

While an occasional whaler was killed by unfriendly or unreceptive islanders, the effect of the ships' landings on the natives was considerably more severe. Unscrupulous captains would often offer to trade for provisions and then sail away without giving anything in return, and it is likely that trigger-happy sailors took the lives of many natives without having to worry about punishment so far from any law but the captain's. In *Nimrod of the Sea*, William Davis recounts the story of three "kanakas" (probably Maoris from New Zealand) who deserted on a tropical island. After demanding their return from the local natives, "the captain doubleshorted his ninepound guns, sent a round into the crowded grass huts of the village, and carried off three natives." From their home ports and pestilent fo'c'sles, the whalemen brought every conceivable communicable disease to the natives, including yaws, influenza, tuberculosis, cholera, syphilis, and the greatest scourge of the unresistant, measles. Prior to exploration, the population of Tahiti was estimated at some 40,000; by 1830, there were only 9000 Tahitians left. A single measles epidemic in 1875 killed nearly 30,000 Fijians.

There was only so much eating, drinking, holystoning of decks, repairing of sails and rigging, and yarn spinning to occupy the sailors on these seemingly endless voyages. To pass the time, some of them created what Clifford Ashley called "the only important indigenous folk art, except for that of the Indians, we have ever had in America: the Art of SCRIMSHAW."

Although there are very few contemporaneous records of scrimshanders at work, probably because the craft was too insignificant to mention, we assume that the whale TEETH were carved during periods of sailing or while waiting in port for provisions or repairs. The baleen of the right and bowhead whales was packed into bundles for commerce at home, but occasionally a piece would be shaped into a busk and decorated with contemporary designs. Baleen was colloquially known to the whalers and merchants of the time as *whalebone*, but it is not bone at all; it is made of keratin, the substance of human hair and fingernails. Whales have bones like any other mammals, but with the exception of the lower jaw—known as the "pan bone"—and the teeth, whale bones are too porous for carving. (Other cultures recognized the attractive nature of whale ivory. Certain Polynesian natives made necklaces of dolphin teeth, and the premissionary Hawaiians crafted the beautiful *le niho palaoa*, a gracefully carved sperm whale tooth that was worn by royalty on a necklace of braided human hair.)

Despite their discomfort, low wages, and even occasional floggings, the crews of whale ships were remarkably docile. The master's word was law, and when the crew became obstreperous, a "taste of the cat" was not unheard of. Only infrequently did they become so desperate that they rebelled. Because harsh treatment, long hours, uncomfortable quarters, and bad food were expected, the whalemen generally endured these indignities in stoic silence. Also, as with any uprising, a

leader is required to galvanize men into action, and on the whale ships, these troublemakers were rare. The story of the *Bounty's* mutiny, which had occurred in 1789—and had nothing whatever to do with whales or whaling—was probably known to every seaman and landlubber on either side of the Atlantic. The fate of Fletcher Christian and the mutineers was not known until 1808, when Captain Mayhew Folger of the Nantucket sealer *Topaz* landed at Pitcairn Island and found the survivors.

On Nantucket Island there lived a young man named Samuel Comstock, who may have heard the tale told by Captain Folger. At the age of 19, after three previous cruises, he shipped out aboard the Nantucket whaler *Globe*, departing from Edgartown on the neighboring island of Martha's Vineyard on December 15, 1822. The ship rounded the Horn on March 5 and stopped briefly at Hawaii before heading for the newly discovered Japan grounds. Despite the reports of plentiful whales off Japan, Captain Worth was unable to locate them, and as they sailed in fruitless circles, the crew became increasingly discontented. Rotten meat was an issue, and conditions were so bad that the captain turned back and headed for Hawaii to reprovision. There several members of the crew deserted, and the *Globe's* depleted crew was replenished with beachcombers and drunkards. Repeated conflicts between officers and crew increased the tension, and when the captain had one of the men flogged, Comstock decided to initiate a mutiny.

On January 26, 1824, Samuel Comstock led his followers in one of the bloodiest mutinies in American naval history. They murdered Captain Worth with an axe, slaughtered first mate Beetle with a boarding knife, shot second mate Lumbard in the mouth and then bayonetted him, and shot third mate Fisher in the back of the head. They heaved the bodies overboard and, with Comstock at the helm, looked for a place where they could land. En route, Comstock decided that one of his crew members was plotting against him, held a "trial," and sentenced him to hang. For 2 weeks they wandered around, uncertain of their location or destination, until they decided to land at tiny Mili Atoll, in what was then known as the Mulgrave Islands and is now known as the Ratak chain of the Marshall Islands. It appears that Comstock's original plan was to arrange things so that he was the only survivor, but the natives and his fellow mutineers conspired against his plan for the perfect mutiny. As Comstock began to give the ship's stores to the natives (to ensure their support), the crew members who had signed on in Hawaii realized that they were in for trouble either from their leader or from the natives, and they shot Comstock dead.

Those members of the crew of the *Globe* who had not participated in the mutiny managed to gain control of the ship and sailed away, leaving the mutineers stranded on the island. They would not last long. A bloody conflict between the natives and the whalemen resulted in the death of all the latter but two: William Lay of Saybrook, Connecticut, and Cyrus Hussey of Nantucket. The *Globe* was sailed to Valparaiso, where the news of the mutiny was made known, and then returned to Nantucket. Her crew was cleared of complicity in the mutiny, and the *Dolphin*, under the command of Lieutenant John ("Mad Jack") Percival, was dispatched to the Pacific to find and bring back the mutineers. Hussey and Lay had been with the natives for almost a year and a half by the time the *Dolphin* arrived, and they looked more like natives than American whalemen. After considerable tension—the Marshallese chiefs were prepared to kill the newly arrived Americans and take their ship—and confusion about who they were, the last of the *Globe's* crew were transported home. Thus ended the story that Starbuck called "the most horrible mutiny that is recounted in the annals of the whale-fishery from any port or nation."

Whaling, Modern

Phillip J. Clapham
Northeast Fisheries Science Center, Woods Hole, Massachusetts

C. Scott Baker
Auckland University, New Zealand

There is no means known to catch the fin whale, or its fast cousins.

So wrote Herman Melville in the year 1851, thus echoing the common lament of whalers that the fastest (and some of the largest) species of whales, such as the finback (*Balaenoptera physalus*) and the blue (*B. musculus*), lay beyond contemporary means of capture. At the time that Melville wrote *Moby Dick*, the basic technology of whaling had remained essentially unchanged for centuries. Whaling ships plied their trade under sail, and the small boats that they lowered to pursue whales were also powered by wind or by the brute strength of their crew's arms at the oars. The killing of whales required men to bring their frail craft alongside the huge quarry, subduing and fastening to it with hand-thrown harpoons. If this dangerous series of actions succeeded, the whale might ultimately be despatched with a lance thrust deep into some vital organ. Once killed, the carcass would be either towed to shore or brought alongside the whaling vessel for the time-consuming process of flensing and "trying out" (boiling) the blubber for oil.

I. The Emergence of Modern Whaling

These methods had been in use in the 11th century when the Basques began the first sustained commercial whale fishery on right whales (*Eubalaena glacialis*) in the Bay of Biscay. Although many improvements had been made, the technology available to whalers in the middle of the 19th century severely limited the number of animals that could be taken and processed in a working day. Furthermore, as Melville noted, it largely precluded exploitation of the faster species. Blue, fin, sei (*B. borealis*), and Bryde's whales (*B. brydei/edeni*), all large and desirable targets, were too swift to allow pursuit by oars or sails. Thus it was the slower species such as the humpback, the right, and the sperm whale (*Physeter macrocephalus*) that had borne the brunt of commercial whaling, and they had done so in some cases for almost a thousand years.

By 1860, however, all of this was about to change. Two men, the Norwegian Svend Føyn and an American named Thomas Welcome Roys, were independently experimenting with explosive harpoons. As patented by Roys in 1861, this device was initially fired from a shoulder gun; Føyn developed a different approach using a bow-mounted cannon, which was to become the industry standard. The "bomb lance" was an innovation that was to revolutionize the whaling industry by providing a much more efficient means to dispatch whales, both quickly and from a distance.

About the same time, the use of sail was beginning to give way to steam. This was a key innovation: together with the explosive harpoon, it radically changed the industry and finally allowed the pursuit and capture of any whale. Suddenly, even the fastest rorquals came under the threat of the harpoon as they were chased down by fast motorized catcher boats.

A further innovation, the compressor, solved a long-standing problem with regard to the many species that did not float when dead: by pumping air into the carcass immediately after death, whalers could secure it before it sank, thus reducing the loss rate greatly.

For the industry, this transition into the mechanized age could not have come at a more opportune time. By 1900, many populations of the traditionally hunted species were commercially exhausted. For some populations, such as the bowhead (*Balaena mysticetus*) and the North Atlantic right whale this was the result of exploitation spread over centuries. With some other stocks, decimation had been accomplished in a remarkably short time: the first North Pacific right whale (*E. japonica*) was not killed until 1835, yet 14 years later the population had already been reduced to the point where many whalers switched their focus to the newly established fishery for bowhead whales in the western Arctic. Another quickly depleted stock was that of the eastern North Pacific gray whale (*Eschrichtius robustus*), made vulnerable by its predictable coastal MIGRATION and tendency to concentrate for breeding and calving in the lagoons of Baja California.

The new technology opened up all species to whaling and did so at a time when the industry, spurred on by steam power, was also expanding geographically. By far the most significant development in this regard was the discovery of the vast stocks of whales in the Southern Ocean. In 1904, the Norwegian whaler C. F. Larsen arrived at the South Atlantic island of South Georgia and reported with astonishment, "I see them in hundreds and thousands." Huge pristine populations of rorquals—notably blues, fin whales, and humpbacks (*Megaptera novaeangliae*)—filled the surrounding waters together with southern right whales (*E. australis*) and other species. Modern whaling had found its last and greatest reserve. A slaughter unparalleled in whaling history was about to begin.

Whaling at South Georgia was initially constrained by the need to use land stations for processing of the carcasses. Be-

cause of this, the time to spoilage limited the range of the catcher boats; it also left the whaling companies vulnerable to high taxes levied by the British authorities. Despite these difficulties, the industry accomplished the destruction of local stocks of whales with remarkable efficiency. At the height of operations, hundreds of humpback, fin, and blue were taken in a single month. By 1915 the South Georgia population of humpbacks had essentially been extirpated, with a total catch of some 18,557 whales; while occasional catches were made in later years (the largest being 238 humpbacks in 1945/1946), the stock was commercially extinct by the time of the Great War. Blue whales suffered a similar fate: 39,296 were killed at South Georgia between 1904 and 1936, at which point the population had crashed, apparently irretrievably.

The problem of dependence on land stations was solved, at a stroke, with the introduction of the factory ship. The British vessel *Lansing* was the first such floating factory and began operations in Antarctic waters in 1925. It is difficult to overestimate the importance of this innovation to whaling or its contribution to the destruction of whale populations in the Antarctic. Factory ships could operate independently far out to sea for months at a time. They maintained round-the-clock processing operations in the long Antarctic days, their huge flensing decks kept constantly supplied by an attendant fleet of catcher boats. Whale carcasses were hauled up the large stern ramp and dismembered with astonishing mechanical efficiency: an adult fin whale of 70 or 80 feet and 100 tons could be rendered from whole animal down to bone in half an hour. With the factory ship, all of Antarctic waters became open to whalers, their operations limited only by the constant dangers of weather and ice.

Over the six decades following the opening of the Antarctic grounds in 1904, the whaling industry killed approximately 2 million whales in the Southern Hemisphere (Table I). This included 360,000 blue whales, some 200,000 humpbacks, more than 400,000 sperm whales, and a staggering 725,000 fin whales (Table 1). By the 1930s, it was apparent even to the whaling nations that some kind of regulation was required. In 1931, the Convention for the Regulation of Whaling was held and adopted worldwide protection for right whales, an action that came into effect in 1935. The second Convention for the Regulation of Whaling was held in 1937 and provided protection for the much-depleted gray whale. However, neither convention went far enough; among other things, because neither Japan nor the Soviet Union ratified these agreements, both were theoretically free to continue killing the only two species that had been granted protection.

TABLE I
Southern Hemisphere Catch Totals (1904–2000)[a]

Blue	360,644
Fin	725,116
Sei	203,538
Humpback	208,359
Bryde's	7,757
Minke	116,568
Right	4,338
Sperm	401,670
Other	11,631
Total	2,039,621

II. Advent of the International Whaling Commission

In 1946, following the virtual cessation of whaling that occurred during World War II, the International Convention for the Regulation of Whaling was developed and signed by all major whaling nations (including Japan and the USSR). Among other things, this landmark convention created the International Whaling Commission (IWC), established to regulate whaling and to oversee research on whale stocks. The latter task had as its principal objective management that would allow the highest viable level of exploitation, a concept widely known as maximum sustainable yield (MSY). This required collection and analysis of information on abundance, population structure, and life history of the great whales to permit setting of quotas.

Unfortunately, the quota system of the IWC was immediately handicapped by an earlier development. In 1932, the whaling nations had developed the "blue whale unit" (bwu). A single bwu was equivalent to one blue whale, two fin whales, two and a half humpbacks, or six sei whales. As such, quotas set in bwu, by permitting whalers to make their own decisions about which whales to take, made no allowance for the conservation status of a particular species, let alone that of a specific population. It was not until 1949 that a species-specific quota (for humpbacks) was established.

The bwu remained in effect until 1972, despite recommendations from IWC scientists as early as 1963 that it be abolished (also in 1963, the same scientists recommended a halt to all humpback and blue whaling; the IWC responded by setting a quota of 10,000 bwu). In some years, the IWC could not agree on a bwu quota, and whaling nations were left to make their own informal agreements on catch levels. Overall, the bwu arguably represents the most ill-conceived and damaging management strategy in IWC history. However, it was far from the only problem in the commission's management of whale populations.

From its inception, the IWC was hampered by the unwillingness of the whaling nations to acknowledge the mounting evidence of decline in whale populations and by the complete lack of any enforcement or independent inspection measures. That the first humpback whale quota in 1949 was immediately exceeded in the three subsequent Antarctic seasons pointedly highlighted the latter issue. Additional examples followed, but it was not until the 1990s that the true extent of this problem became apparent, and it was more egregious than anyone could have predicted.

In 1993, following the end of the Cold War, former Soviet biologists revealed that the USSR had conducted a massive

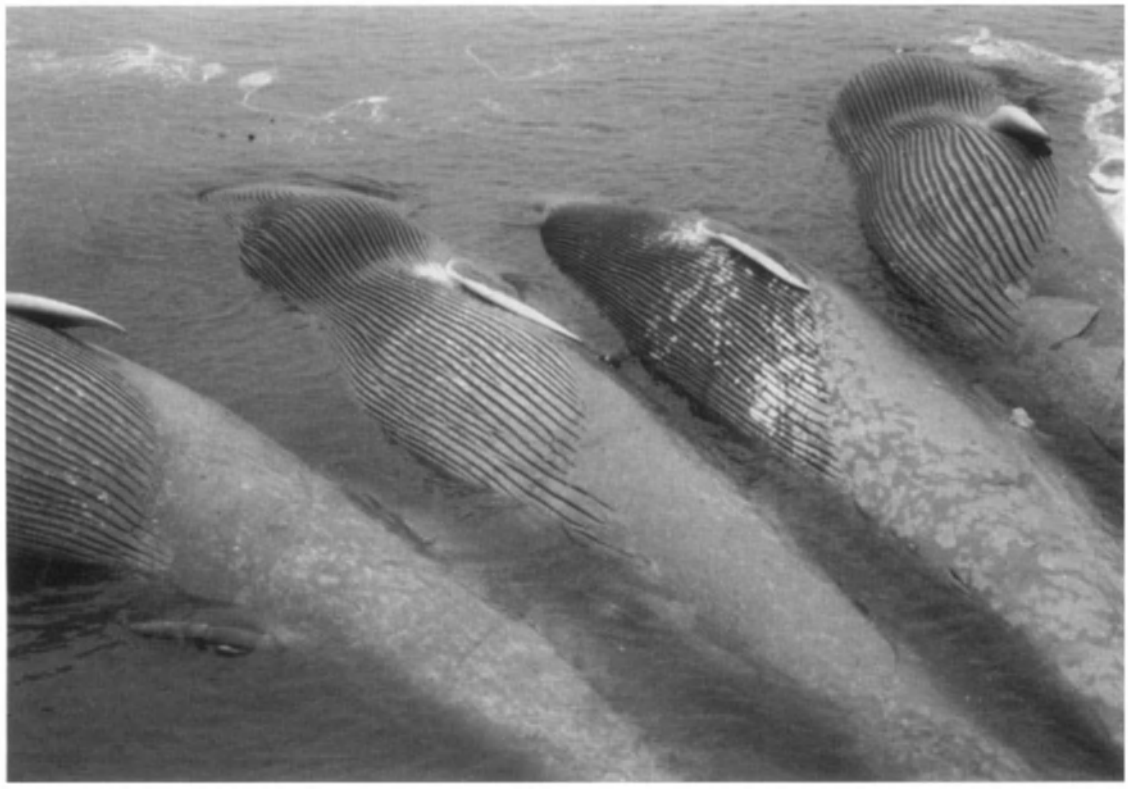

Figure 1 *These blue whales are among those harvested worldwide during the 20th century. Over 360,000 animals were harvested from the Southern Hemisphere alone. Photo by Whales Research Institute, courtesy of Hideo Omura.*

campaign of illegal whaling beginning shortly after World War II. Soviet factory fleets had killed virtually all whales they encountered, irrespective of size, age, or protected status. The scale of this deception was staggering: in all, the difference between the reported take of the USSR and its actual catches was more than 100,000 animals in the Southern Hemisphere alone (Table II). Of these, the humpback whale was the most heavily impacted: reporting 2710 catches to the IWC, the Soviets had in fact taken more than 48,000. In the Northern Hemisphere, Soviet activities were on a smaller scale, but were nonetheless extremely damaging in some cases. The virtual disappearance of right whales in the eastern North Pacific in the 1960s was recently explained by revelations of Soviet catches of 372 whales from this already depleted stock between 1963 and 1967.

In retrospect, it is possible to see clues to this unfolding catastrophe. Beginning in 1959, at a time when there was increasing discussion of declining populations and the need for diminished quotas, the Soviets began adding a new factory ship each year to their Antarctic fleet. This included the *Sovetskaya Ukraina*, the largest floating factory ever built, with an attendant fleet of 25 catcher vessels. In a single season (1959/1960), *Sovetskaya Ukraina* and a second factory, the *Slava*, killed almost 13,000 humpbacks, mainly from the high-latitude waters south of Australia, New Zealand, and western Oceania. In addition, the intransigence of the USSR in its opposition to a proposed international observer scheme (IOS, to permit independent inspections of catches at sea) is now easy to interpret. The illegal catches continued until adoption and implementation of the IOS was finally accomplished in the early 1970s.

In the latter part of the 1960s the IWC finally began to respond to the increasing evidence that whale populations had been exploited well beyond MSY. Blue whales were protected in 1965, and quotas for fin and sei whales were reduced in the late 1960s in response to declines in catches. Nonetheless, any enforcement remained absent, and the Soviets secretly continued to kill whales irrespective of quota or protection.

III. The Decline of Commercial Whaling

In the following decade, however, a sea change occurred at the IWC. The composition of the commission slowly shifted as nonwhaling nations joined, while others ceased whaling and developed instead into advocates for conservation. A whaling moratorium was proposed by the United States and Mexico as early as 1974, but this and later proposals were rejected by IWC until 1982. In that year, a radically changed commission finally achieved the necessary votes to pass a 10-year moratorium. Predictably, Japan, Norway, and the Soviet Union objected. The moratorium went into effect in 1986, with a zero catch quota for both pelagic and coastal whaling.

TABLE II
Reported versus Actual Catches by the USSR[a]

	Reported	*Actual*
Blue	3,651	3,642
Pygmy blue	10	8,439
Fin	52,931	41,184
Sei	33,001	50,034
Humpback	2,710	48,477
Bryde's	19	1,418
Minke	17,079	14,002
Right	4	3,212
Sperm	74,834	89,493
Other	1,539	1,745
Total	185,778	261,646

[a]Note that some catches were actually overreported; this was to disguise takes of protected species by overreporting catches of species that were legally huntable at the time. From Yablokov *et al.* (1998).

At this point in time Soviet whaling was coming to an end; with aging capital and the imminent dissolution of the USSR, the nation that had wreaked so much havoc on whale populations (a fact still unknown at this time) slowly removed itself from the business of commercial whaling. Japan, Norway, and Iceland, however, remained active, and in 1987 they effectively circumvented the moratorium by beginning "scientific" whaling. This act exploited a provision in the convention that allows member nations to issue themselves permits to conduct whaling for scientific research; it was originally included at a time when the only way in which any information could be gathered about whales was to kill them. As opponents of scientific whaling pointed out, the emergence in the 1970s of long-term studies of living whales (frequently based on the IDENTIFICATION of individual animals) provided a much better means to study the biology and behavior of cetaceans.

The stated reason for the moratorium was to permit world whale stocks to recover from the overexploitation to which they had been subject. In the meantime, the IWC's scientific committee was charged with developing a new management procedure for future management of stocks and setting of quotas. After considerable debate, the so-called revised management procedure (RMP) was accepted by the scientific committee in 1994. The RMP is a computer model for determining the level of allowable commercial catches for a stock based on its current abundance, history of exploitation, levels of incidental takes, and overlap with adjacent stocks having differing catch histories. However, the scheme by which the RMP would actually be implemented had still not been adopted in 2001, and there remains considerable resistance to the idea of the IWC endorsing a program that would effectively permit the resumption of commercial whaling. In 1994, Norway preempted such an agreement by resuming commercial whaling under "objection" to the moratorium and used the RMP to set its own catch quotas for minke whales in the northeastern North Atlantic.

The reluctance of many nations to implement the RMP stems largely from lingering concerns regarding enforcement and transparency in whaling operations. The whaling nations maintain that adequate measures are now in place to ensure compliance with quotas set under the RMP. Opponents disagree, pointing to the history of deception in modern whaling and noting more recent evidence that such deception continues to exist. In particular, considerable attention has been focused on the use of forensic genetics to test samples of whale meat in Japanese markets; although the only meat that should be found there is that from minke whales (*B. acutorostrata* and *B. bonaerensis*) taken in Japanese scientific catches, numerous other species have been detected. Although some of these animals probably represent bycatch (incidental entrapment in fishing gear), their presence reinforces the fact that there is currently no means to adequately track whale products at every stage from catch to market. A DNA register of all animals taken in Japanese and Norwegian hunts has been proposed, but it has yet to be fully developed and accepted by the IWC; the resolution of this issue is not aided by the whaling nations' insistence that any discussion of trade in whale products lies within the purview not of the IWC but rather of the Convention on International Trade in Endangered Species (CITES) or the World Trade Organization.

IV. Impacts of Whaling on the Stocks of Whales

The impact of modern whaling on the world's stocks of whales has been varied. Many species appear to be recovering despite past exploitation, which in many cases may have reduced numbers by 90% or more from pristine levels. Humpback whales, which were extensively overhunted worldwide and which bore the brunt of illegal Soviet catches in the Southern Hemisphere, are showing strong rates of population growth in the North Atlantic, North Pacific, and some areas of the Southern Ocean. Eastern gray whales number approximately 26,000 animals and have been removed from the U.S. list of endangered species. Although no reliable estimates of abundance exist, populations of fin and sei whales are assumed to be healthy in the Northern Hemisphere; the status of the extensively exploited Antarctic populations is less clear. Similarly, sperm whales are likely to be generally abundant, although in some areas, apparently slow rates of population growth may be attributable to overexploitation of mature males in high latitudes, resulting in insufficient availability of mates that are "acceptable" to adult females. Although there is considerable controversy over Japanese and Norwegian whaling, there is general agreement that some of the targeted stocks of minke whales are abundant. However, some adjacent stocks are considered depleted and could be impacted in areas where the whales mix during migration.

In contrast, other populations of whales appear to be struggling to recover from the indiscriminate exploitation to which they were subject. In some extreme cases, local populations appear to have been extirpated, with no recovery evident in the intervening years. Humpback and blue whales at South Georgia were commercially extinct by 1915 and 1936, respectively,

and are rarely observed there today. Blue whales were wiped out from the coastal waters of Japan by about 1948, and no members of this species have been recorded there in recent years despite an often extensive survey effort. Off Gibraltar, a population of fin whales was extirpated with remarkable speed between 1921 and 1927. The population of humpbacks that used the coastal waters of New Zealand as a migratory route crashed in 1960 as a result of shore whaling and the 1959/1960 Soviet catches of almost 13,000 humpbacks in the feeding grounds to the south. A few sightings have been reported off New Zealand in recent years, perhaps suggesting that a slow recovery is underway. In the North Atlantic, right whales were removed from much of their former range largely by historical whaling prior to 1880 (the Labrador stock seems to have been wiped out by Basque whaling as early as 1610), but even here, a remnant population in European waters was extirpated by Norwegians using modern techniques at the beginning of the 20th century. The demise of at least one stock of whales can be attributed exclusively to premodern whaling: the bowhead was commercially extinct from Spitsbergen waters by 1900, and the species is rarely observed there today.

In all of these cases, whaling essentially extirpated a stock of whales. The lack of recovery over a time scale ranging from four decades in the case of New Zealand humpbacks to almost four centuries for right whales off Labrador has important implications for the modern MANAGEMENT of whale populations. Although it is quite likely that the observed lack of recovery was at least partly due to a simultaneous overexploitation of adjacent populations (i.e., those that might otherwise have provided a source for repopulation), these localized extirpations reinforce the belief that management units should be designed carefully on often smaller spatial scales than has been the case in the past.

Of those populations that survived, several are critically endangered. Right whales persist in low numbers in the western North Atlantic and the western North Pacific; the present size of the eastern North Pacific population is unknown, but is clearly precariously small following the immense damage done by the Soviets in the 1960s. In sharp contrast to the eastern ("California") gray whale, the outlook for the western North Pacific population of this species is bleak. Whaling on this small stock continued in Korean waters into the 1960s. and a gray whale was found harpooned in Japan as recently as 1996. Only a hundred or so animals may remain extant today. Furthermore, nothing is known of the location of the breeding grounds for this population; if it is reliant on coastal lagoons for calving (as is a major segment of the eastern stock), the impact of coastal development and other human activities may be severe. Among bowhead populations, that in the Bering/Beaufort/Chukchi Seas is recovering strongly despite continued exploitation by a well-managed Inuit hunt. In the eastern Arctic, a few hundred bowheads remain in Canadian waters (principally Hudson Bay/Foxe Basin and Baffin Bay/Davis Strait), while as noted earlier the Spitsbergen stock appears to be functionally extinct. Finally, blue whales have fared poorly almost everywhere; the only population that appears to be large and healthy is that which feeds off California in summer. Other blue whales, including all of those in the Southern Ocean, remain rare and highly endangered.

It is not clear what the future holds for whaling. Ultimately, it depends on the outcome of developing geopolitics: put simply, on whether the emerging worldview of commercial whaling as an anachronism prevails or, if it does not, on whether whaling can learn the lessons of its grim past. For now, the outcome remains hung in the balance.

White-Beaked Dolphin

Lagenorhynchus albirostris

CARL CHRISTIAN KINZE
Zoological Museum, University of Copenhagen, Denmark

Recognized only as a separate species in 1846, the white-beaked dolphin was among the last of the commonly occurring North Atlantic dolphins species to enter the cetological theater. Earlier finds remain obscure because they have been confused with bottlenose (*Tursiops truncatus*) or common dolphins (*Delphinus* spp).

The white-beaked dolphin was described twice in 1846, first by the English cetologist Edward Gray based on an animal that was caught off Great Yarmouth, England, and almost simultaneously by the Danish cetologist Daniel F. Eschricht, who described a specimen from the west coast of Jutland, Denmark, under the name *Delphinus ibsenii.*

Figure 1 *A white-beaked dolphin stranded on the Danish west coast. Photograph courtesy of Martin Abrahamsson, Midtsønderjyllands Museum, Gram, Denmark.*

I. Vernacular Names

Vernacular names of the species in most languages depict the white beak: Weissschnauzen-Delphin (German), dauphin avec bec blanc (French), delfin de hocico blanco (Spanish) Witsnuitdolfijn (Dutch), hvidnæse (Danish), kvitnos or hvitnos (Norwegian), and vitnosdelfin (Swedish).

II. Description

The white-beaked dolphin has a robust appearance. The short beak is usually only between 5 and 8 cm long. There is an erect falcate dorsal fin in the middle of the back. Adults grow between 2.4 and 3.1 m long and may weigh between 180 and 350 kg. Males usually grow larger than females. Newborn animals are 1.2 m long and weigh about 40 kg. There are 25–28 conical teeth in each half of the upper and lower jaws.

The COLORATION is typically black on the back with a white saddle behind the dorsal fin and whitish bands on the flanks that vary in intensity from shining white to ashy gray. The belly and beak are normally white (Figs. 1 and 2). The white beak is sometimes ashy gray or even darker, giving the appearance that the white beak is missing.

III. Distribution

The species is endemic to the temperate and subarctic North Atlantic (Fig. 3). It is frequently sighted in shelf waters and sometimes also dwells in shallow coastal waters. However, it has less oceanic preference than its congener the Atlantic white-sided dolphin (*Lagenorhynchus acutus*). Populations in the eastern and western part of its range have been distinguished by means of skull measurements and osteological features.

In the northeast Atlantic it can be found as far north as the White Sea. It is abundant along the Norwegian coasts and in the northern parts of the North Sea and is not uncommon in the southern North Sea along the seaboard of the United Kingdom, Belgium, the Netherlands, Germany, and Denmark. In certain years small schools or individuals may enter the Kattegat, Danish Straits, and even the Baltic proper: a phenomenon believed to be caused by an increased saline influx to the Baltic Sea. The white-beaked dolphin is also known from the French, Spanish Atlantic coasts and may irregularly reach as far south as the Strait of Gibraltar.

In the northwest Atlantic the species seems to be less abundant. The largest concentrations are found off the Labrador coast and in southwest Greenland, but individuals have been encountered as far south as Cape Cod.

IV. Behavior

Schools of up to 30 animals are common, but much larger schools consisting of several hundred or even thousands of animals have sometimes been recorded. The school structure is not known. Animals can be inquisitive and may approach vessels readily. The aerial behavior is very spectacular and typically

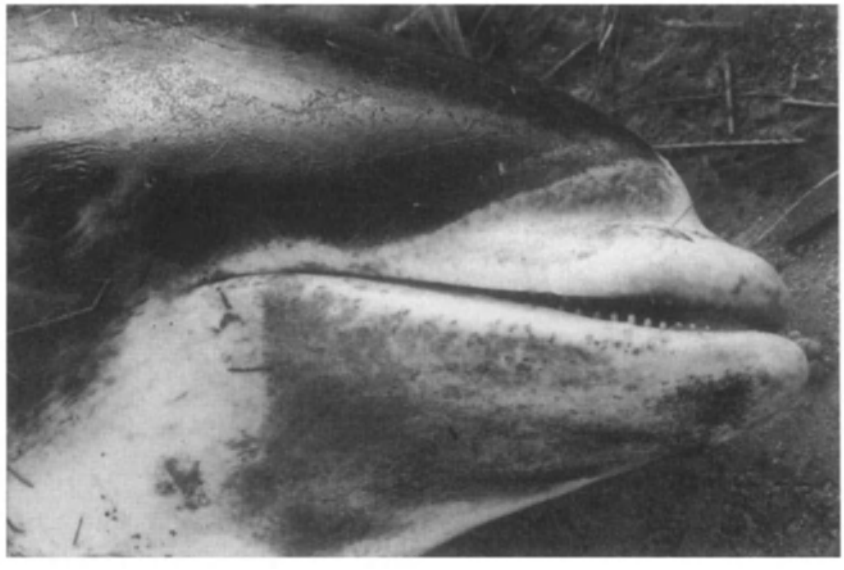

Figure 2 *Close-up of the beak. Photograph courtesy of Martin Abrahamsson, Midtsønderjyllands Museum, Gram, Denmark.*

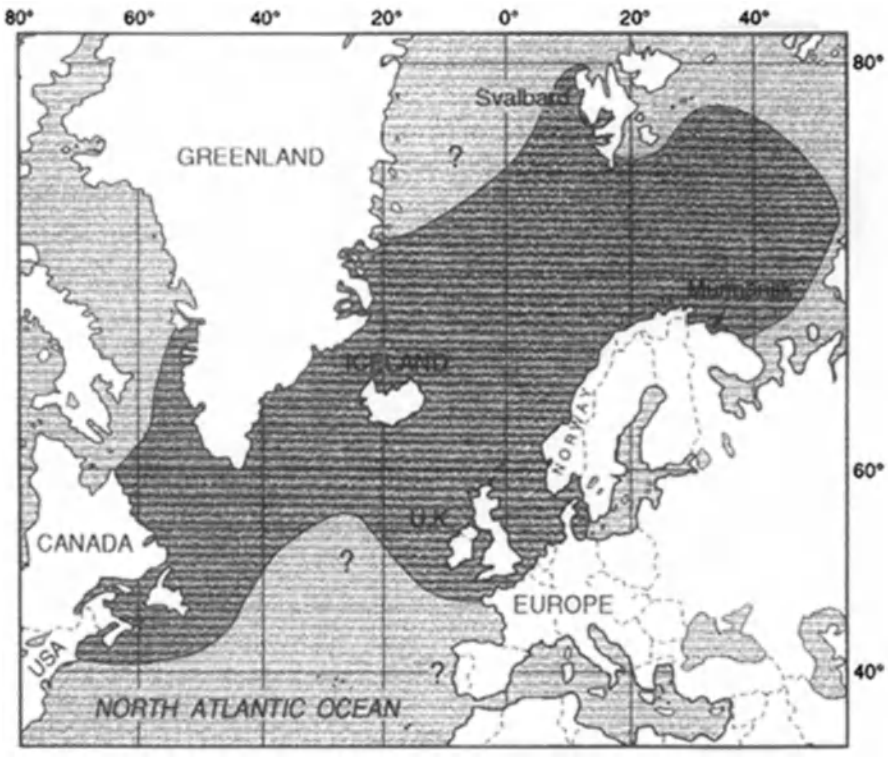

Figure 3 *Distribution of the white-beaked dolphin.*

dolphin-like. Under good sighting conditions the "rooster tail splash" created during speedy swimming is easily visible. The white-beaked dolphin may ride the bow wave of ships and larger whales. The DIVING BEHAVIOR is not known in detail. Mixed schools with white-sided dolphins have been recorded.

V. Reproduction

The available information on reproductive parameters is rather limited. Females reach sexual maturity at about 240 cm in length whereas males mature when around 250 cm long. The age at sexual maturity is not known. Births occur during summer, and gestation lasts between 10 and 11 months. The duration of lactation is not known.

VI. Diet and Natural Enemies

The diet consists of mesopelagic fish species, especially cod, whiting, and other gadids, as well as squids.

Killer whales and also larger shark species probably pose the only natural threat to white-beaked dolphins.

VII. Human Interaction

There is no commercial harvesting of the species. A few animals are shot off southwest Greenland every year. INCIDENTAL CATCHES have occurred in trawls and bottom gill nets (mainly young animals).

MARINE MAMMAL SPECIES[a]

ORDER CARNIVORA

Family Otariidae

Arctocephalus pusillus (Schreber, 1775), Tasmanian and Cape fur seals
Arctocephalus gazella (Peters, 1875), Antarctic fur seal
Arctocephalus tropicalis (Gray, 1872), Subantarctic fur seal
Arctocephalus townsendi Merriam, 1897, Guadalupe fur seal
Arctocephalus philippii (Peters, 1866), Juan Fernández fur seal
Arctocephalus forsteri (Lesson, 1828), South Australian and New Zealand fur seals
Arctocephalus australis (Zimmerman, 1783), South American fur seal
Arctocephalus galapagoensis Heller, 1904, Galapagos fur seal
Callorhinus ursinus (Linnaeus, 1758), Northern fur seal
Zalophus japonicus (Peters, 1866), Japanese sea lion
Zalophus californianus (Lesson, 1828), California sea lion
Zalophus wollebaeki Sivertsen, 1953, Galapagos sea lion
Eumetopias jubatus (Schreber, 1776), Steller sea lion, northern sea lion
Neophoca cinerea (Péron, 1816), Australian sea lion
Phocarctos hookeri (Gray, 1844), New Zealand sea lion, Hooker's sea lion
Otaria flavescens (Shaw, 1800), South American sea lion

Family Odobenidae

Odobenus rosmarus (Linnaeus, 1758), Walrus

Family Phocidae

Erignathus barbatus (Erxleben, 1777), Bearded seal
Phoca vitulina (Linnaeus, 1758), Harbor seal, common seal
Phoca largha (Pallas, 1811), Spotted seal, larga seal
Pusa hispida (Schreber, 1775), Ringed seal
Pusa caspica (Gmelin, 1788), Caspian seal
Pusa sibirica (Gmelin, 1788), Baikal seal
Halichoerus grypus (Fabricius, 1791), Gray seal
Histriophoca fasciata (Zimmerman, 1783), Ribbon seal
Pagophilus groenlandicus (Erxleben, 1777), Harp seal
Cystophora cristata (Erxleben, 1777), Hooded seal
Monachus tropicalis (Gray, 1850), Caribbean monk seal, West Indian monk seal
Monachus monachus (Hermann, 1779), Mediterranean monk seal
Monachus schauinslandi Matschie, 1905, Hawaiian monk seal
Mirounga leonina (Linnaeus, 1758), Southern elephant seal
Mirounga angustirostris (Gill, 1866), Northern elephant seal
Leptonychotes weddellii (Lesson, 1826), Weddell seal
Ommatophoca rossii Gray, 1844, Ross seal
Lobodon carcinophaga (Hombron and Jacquinot, 1842) Crabeater seal
Hydrurga leptonyx (Blainville, 1820), Leopard seal

Family Ursidae

Ursus maritimus Phipps, 1774, Polar bear

[a]Living and recently extinct. Author(s) and year of description of the species follow the Latin species name; when these are enclosed in parentheses, species was originally described in a different genus. Classification and scientific names follow Rice (1998), with the exception of the right whales (*Eubalaena* spp.) and the marine otter. Recent genetic evidence strongly supports the recognition of three separate species of right whales (Rosenbaum *et al.*, 2000). In addition, the genus *Eubalaena* (rather than *Balaena* as in Rice, 1998) is retained for the right whales as recommended by the Scientific Committee of the IWC (IWC, 2001). The use of *Lontra* rather than *Lutra* for the marine otter follows Larivière (1998) in recognizing the otters of North and South America as a monophyletic taxon distinct from the otters of Eurasia. For the rest, we do not necessarily endorse Rice's (1998) classification and usage in all their details but have used them as a standard, based on the recent literature, to avoid editorial confusion in the volume.

Family Mustelidae
Enhydra lutris (Linnaeus, 1758), Sea otter
Lontra felina (Molina, 1782), Marine otter, chungungo

ORDER CETACEA

Suborder Mysticeti

Family Balaenidae
Eubalaena glacialis (Müller, 1776), North Atlantic right whale
Eubalaena japonica (Lacépède, 1818), North Pacific right whale
Eubalaena australis (Desmoulins, 1822), Southern right whale
Balaena mysticetus Linnaeus, 1758, Bowhead whale, Greenland whale

Family Neobalaenidae
Caperea marginata (Gray, 1846), Pygmy right whale

Family Eschrichtiidae
Eschrichtius robustus (Liljeborg, 1861), Gray whale

Family Balaenopteridae
Megaptera novaeangliae (Borowski, 1781), Humpback whale
Balaenoptera acutorostrata Lacépède, 1804, Common minke whale
Balaenoptera bonaerensis Burmeister, 1867, Antarctic minke whale
Balaenoptera edeni Anderson, 1879, Pygmy Bryde's whale, Sittang whale
Balaenoptera brydei Olsen, 1913, Common Bryde's whale
Balaenoptera borealis Lesson, 1828, Sei whale
Balaenoptera physalus (Linnaeus, 1758), Fin whale, finback whale
Balaenoptera musculus (Linnaeus, 1758), Blue whale

Suborder Odontoceti

Family Physeteridae
Physeter macrocephalus Linnaeus, 1758, Sperm whale

Family Kogiidae
Kogia breviceps (Blainville, 1838), Pygmy sperm whale
Kogia sima (Owen, 1866), Dwarf sperm whale

Family Ziphiidae
Ziphius cavirostris G. Cuvier, 1823, Cuvier's beaked whale, goose-beaked whale
Berardius arnuxii Duvernoy, 1851, Arnoux' beaked whale
Berardius bairdii Stejneger, 1883, Baird's beaked whale
Tasmacetus shepherdi Oliver, 1837, Shepherd's beaked whale, Tasman beaked whale
Indopacetus pacificus (Longman, 1926), Indo-Pacific or Longman's beaked whale
Hyperoodon ampullatus (Forster, 1770), North Atlantic bottlenose whale
Hyperoodon planifrons (Flower, 1882), Southern bottlenose whale
Mesoplodon hectori (Gray, 1871), Hector's beaked whale
Mesoplodon mirus True, 1913, True's beaked whale
Mesoplodon europaeus (Gervais, 1855), Gervais' beaked whale
Mesoplodon bidens (Sowerby, 1804). Sowerby's beaked whale
Mesoplodon grayi von Hast, 1876, Gray's beaked whale, scamperdown whale
Mesoplodon peruvianus Reyes, Mead and Van Waerebeek, 1991, Pygmy beaked whale, Peruvian beaked whale
Mesoplodon bowdoini Andrews, 1908, Andrew's beaked whale
Mesoplodon bahamondi Reyes, Van Waerebeek, Cárdenas and Yáñez, 1996, Bahamonde's beaked whale
Mesoplodon carlhubbsi Moore, 1963, Hubbs' beaked whale
Mesoplodon ginkgodens Nishiwaki and Kamiya, 1958, Ginkgo-toothed beaked whale
Mesoplodon stejnegeri True, 1885, Stejneger's beaked whale
Mesoplodon layardii (Gray, 1865), Layard's or strap-toothed beaked whale
Mesoplodon densirostris (Blainville, 1817), Blainville's or dense-beaked whale

Family Platanistidae
Platanista gangetica (Roxburgh, 1801), Susu, bhulan, South Asian river dolphin, Indian river dolphin

Family Iniidae
Inia geoffrensis (Blainville, 1817), Boto, Amazon river dolphin

Family Lipotidae
Lipotes vexillifer (Miller, 1918), Baiji, Yangtze river dolphin

Family Pontoporiidae
Pontoporia blainvillei (Gervais and d'Orbigny, 1821), Franciscana, La Plata river dolphin

Family Monodontidae
Monodon monoceros Linnaeus, 1758, Narwhal
Delphinapterus leucas (Pallas, 1776), Beluga, belukha, white whale

Family Delphinidae

Cephalorhynchus commersonii (Lacépède, 1804), Commerson's dolphin
Cephalorhynchus eutropia (Gray, 1846), Chilean dolphin
Cephalorhynchus heavisidii (Gray, 1828), Haviside's dolphin
Cephalorhynchus hectori (van Bénéden, 1881), Hector's dolphin
Steno bredanensis (G. Cuvier *in* Lesson, 1828), Rough-toothed dolphin
Sousa teuszii (Kükenthal, 1892), Atlantic hump-backed dolphin
Sousa plumbea (G. Cuvier, 1829), Indian hump-backed dolphin
Sousa chinensis (Osbeck, 1765), Pacific hump-backed or Chinese white dolphin
Sotalia fluviatilis (Gervais and Deville, 1853), Tucuxi
Tursiops truncatus (Montagu, 1821), Common bottlenose dolphin
Tursiops aduncus (Ehrenberg, 1833), Indian Ocean or Indo-Pacific bottlenose dolphin
Stenella attenuata (Gray, 1846), Pantropical spotted dolphin
Stenella frontalis (G. Cuvier, 1829), Atlantic spotted dolphin
Stenella longirostris (Gray, 1828), Spinner dolphin
Stenella clymene (Gray, 1850), Clymene dolphin
Stenella coeruleoalba (Meyen, 1853), Striped dolphin
Delphinus delphis Linnaeus, 1758, Short-beaked common dolphin
Delphinus capensis Gray, 1828, Long-beaked common dolphin
Delphinus tropicalis van Bree, 1971, Indian Ocean common dolphin
Lagenodelphis hosei Fraser, 1956, Fraser's dolphin
Lagenorhynchus albirostris (Gray, 1846), White-beaked dolphin
Lagenorhynchus acutus (Gray, 1828), Atlantic white-sided dolphin
Lagenorhynchus obliquidens Gill, 1865, Pacific white-sided dolphin
Lagenorhynchus obscurus (Gray, 1828), Dusky dolphin
Lagenorhynchus australis (Peale, 1848), Peale's dolphin
Lagenorhynchus cruciger (Quoy and Gaimard, 1824), Hourglass dolphin
Lissodelphis borealis Peale, 1848, Northern right whale dolphin
Lissodelphis peronii (Lacépède, 1804), Southern right whale dolphin
Grampus griseus (G. Cuvier, 1812), Risso's dolphin, gray grampus
Peponocephala electra (Gray, 1846), Melon-headed whale, Electra dolphin
Feresa attenuata Gray, 1874, Pygmy killer whale
Pseudorca crassidens (Owen, 1846), False killer whale
Orcinus orca (Linnaeus, 1758), Killer whale, orca
Globicephala melas (Traill, 1809), Long-finned pilot whale
Globicephala macrorhynchus Gray, 1846, Short-finned pilot whale
Orcaella brevirostris (Owen *in* Gray, 1866), Irrawaddy dolphin, pesut

Family Phocoenidae

Neophocaena phocaenoides (G. Cuvier, 1829), Finless porpoise
Phocoena phocoena (Linnaeus, 1758), Harbor porpoise, common porpoise
Phocoena sinus (Norris and McFarland, 1958, Vaquita, Gulf of California harbor porpoise
Phocoena spinipinnis Burmeister, 1865, Burmeister's porpoise
Phocoena dioptrica Lahille, 1912, Spectacled porpoise
Phocoenoides dalli (True, 1885), Dall's porpoise, Dall porpoise

ORDER SIRENIA

Family Trichechidae

Trichechus manatus Linnaeus, 1758, Caribbean manatee, West Indian manatee
Trichechus senegalensis Link, 1795, African manatee, West African manatee
Trichechus inunguis (Natterer, 1883), Amazon manatee

Family Dugongidae

Dugong dugon (Müller, 1776), Dugong, sea cow
Hydrodamalis gigas (Zimmerman, 1780), Steller's sea cow, giant sea cow

BIOGRAPHIES

Science is done by individuals, and the student or practicing scientist often wants to know something about those who came before, who developed the field. The brief biographies listed here are meant to meet that need, however sketchily. The list includes those who, in the opinion of the editors, made an important and lasting contribution to the study of marine mammals. Some of their most important works are also listed, and the student is urged to peruse some of these classics. Living persons are not included, as lifetime contributions cannot be fairly weighed until they are completed.

Abel, Othenio (1875–1946) Austrian paleontologist, the main European researcher on fossil whales in the early 20th century, working on the Belgian Miocene and on *Basilosaurus*. He expanded the perspective of marine mammal paleontologists to include higher-level phylogeny.

Abel, O. (1905). Les Odontocétes du Bolderien (Miocene superieure) d'Anvers. *Mem. Mus. roy. Hist. nat. Belg.* **3**, 1–155.

Abel, O. (1907). The genealogical history of the marine mammals. *Ann. Rep. Smithson. Inst.*, **1907**, 473–496.

Allen, Glover M. (1879–1942) One of the great naturalists of his day; among his enduring works relating to marine mammals are his monograph on the baleen whales of New England and his 1942 book on extinct and endangered mammals, which included the first review of the status of marine mammal species and the conservation problems affecting them.

Allen, G. M. (1916). The whalebone whales of New England. *Mem. Boston Soc. Nat. Hist.* **8**, 109–322.

Allen, G. M. (1942). "Extinct and Vanishing Mammals of the Western Hemisphere with the Marine Species of All the Oceans." American Committee for International Wildlife Protection, Cambridge, Massachusetts. (1972 reprint by Cooper Square, New York).

Allen, Joel A. (1838–1921) Completed the first comprehensive bibliography of cetology and sirenology (1495–1840), which is still highly useful today. He also produced a series of important monographs and papers on the marine mammals of North America.

Allen, J. A. (1880). History of North American pinnipeds: A monograph of the walruses, sea-lions, sea-bears and seals of North America. *U.S. Geol. Surv. Terr. Misc. Pub.* **12**, 1–785.

Allen, J. A. (1881). Preliminary list of works and papers relating to the mammalian orders Cete and Sirenia. *Bull. U.S. Geol. Geogr. Surv. Terr.* **6**, 399–562.

Allen, J. A. (1908). The North Atlantic right whale and its near allies. *Bull. Am. Mus. Nat. Hist.* **24**, 277–329, pl. 19–24.

Andrews, Roy Chapman (1884–1960) Paleontologist, cetologist, educator, and popularizer at the American Museum of Natural History in New York, he traveled the world and authored many important technical papers and monographs as well as best-selling popular books. His cetological work covered porpoises, beaked whales and baleen whales.

Andrews, R. C. (1916). "Whale Hunting with Gun and Camera." Appleton, New York.

Arsen'ev, Viktor Alexandrovich (1908–1991) Noted biologist who produced or co-authored several important works on Russian marine mammals; his research focused on the northern fur seal. (See also SOKOLOV.)

Arsen'ev, V. A., and Zemskiy, V. A. (1954). ["In the Land of Whales and Penguins"]. Moskovkiy Gos. Universitet, Moscow. (In Russian).

Zemskiy, V. A., Arsen'ev V. A. and Studenezskaya, I. S. (1973). ["Marine Mammals"]. Pistchevaya Promyshlenost', Moscow.

Bélon du Mans, Pierre (1517–1566) Arguably the first cetologist since Aristotle and Pliny more than a millennium earlier, Bélon was the first to mention cetaceans in the title of a zoological work. The book included an account of the anatomy of a porpoise and listed seven species of whales, dolphins and porpoises. Figures in his second book were much copied by later workers.

Bélon, P. (1541). "L'Histoire Naturelle des Estranges Poissons Marins, avec la vraie Peincture et Description du Dauphin et de plusieurs autres de son espèce." Regnaud Chaudière, Paris.

Belloni, P. (1553). "De aquatilibus, Libri duo." Stephan, Paris.

Berzin, Alfred A. (1930–1996) Latvian whale biologist, born in Rostov-on-Don, Russia; known for his comprehensive research and monograph on the sperm whale. He spent his career at the Pacific Ocean Research Institute for Fisheries and Oceanography (TINRO) in Vladivostock. Most recently, he took part in the recovery and reporting of the true Soviet whaling catch data, which exposed massive unreported kills of protected whales in the 1960s and 1970s that may explain the apparent failure of some stocks to recover.

Bigg, Michael A. (1939–1990) Born in London and emigrating to British Columbia as a child, he was the first to use individual identification of killer whales to study long-term social structure, life history and movements. He discovered the existence of sympatric but non-mixing fish-eating and mammal-eating forms/groups ("residents" and "transients") and established the fact that killer whale pods are matrilineal groups, with all offspring remaining with the maternal pod.

Bigg, M. A., Olesiuk, P. F., Ellis, G. M., Ford, J. K. B., and Balcomb, K. C. (1990). Social organization and genealogy of resident killer whales (*Orcinus orca*) in the coastal waters of British Columbia and Washington State. *Rep. Int. Whal. Commn. (Spec. Iss.)* **12**, 383–405.

Bonner, W. Nigel (1928–1994) Biologist at the British Antarctic Survey and a major and primary contributor to the biology, assessment and management of the southern elephant seal, other Antarctic pinnipeds, and British seals. He authored several technical and semi-popular books.

Bonner, W. N. (1968). The fur seal of South Georgia. *Brit. Ant. Surv. Sci. Rep.* **56**, 1–81.

Bonner, W. N. (1990). "The Natural History of Seals." Facts on File, New York.

Caldwell, David K. (1928–1990) Cetologist and historian born in Louisville, Kentucky, David Caldwell with his wife and research partner acoustician Melba C. Caldwell discovered that dolphins have individual "signature whistles." He founded and edited the journal *Cetology*.

Caldwell, M. C., and Caldwell, D. K. (1965). Individualized whistle contours in bottlenose dolphins (*Tursiops truncates*). *Nature* **207**, 434–435.

Caldwell, D. K., and Caldwell, M. C. (1972). "The World of the Bottlenose Dolphin." J. B. Lippincott, Philadelphia.

Chapman, Douglas G. (1920–1996) Noted mathematician, wildlife scientist, and teacher, born in Canada and spending his career at the University of Washington in Seattle. He was a member of the famous Committee of Three Scientists established by International Whaling Commission in 1961 as an independent body to advise on status and trends of whale stocks, leading to accurate predictions of collapse of stocks under commercial exploitation. A pioneer in the development and use of quantitative models for marine mammal assessment and management, he worked on pinnipeds as well as cetaceans.

Chapman, D. G. (1961). Population dynamics of the Alaska fur seal herd. *Trans. N. Am. Wildl. Conf.* **26**, 356–369.

Chapskiy, Konstantin Konstantinovich (1906–1984) The preeminent Russian pinniped biologist of the mid-20th century, he concentrated on the systematics of the phocid seals but also worked on the ecology and morphology of other groups.

Chapskiy, K. K. (1941). ["Marine Animals of the Soviet Arctic"]. Izdatel. Glav., Moscow.

Chapskiy, K. K. (1955). [An attempt at revision of the systematics and diagnostics of seals of the subfamily Phocinae]. *Trud. Zool. Inst. Akad. Nauk SSSR* **17**, 161–199. (*Fish. Res. Bd Can. Transl. Ser.* **114**, 1–57 (1957)).

Chapskiy, K. K. and Sokolov, V. E. (1975). "Morphology and Ecology of Marine Mammals: Seals, Dolphins, Porpoises." Wiley, New York.

Cuvier, Frederic (1773–1838) Comparative anatomist and physiologist, brother of Georges Cuvier; Frederic Cuvier synthesized the available information on cetaceans in his landmark volumes, correcting many errors about cetacean natural history accumulated through the centuries.

Cuvier, F. (1829). Cétacés. *In* "Histoire Naturelle des Mamifères" (E. Geoffroy Saint-Hilaire and F. Cuvier.

Cuvier, F. (1836). "De l'Histoire Naturelle des Cétacés." Roret, Paris.

Cuvier, Georges (1769–1832) Famed paleontologist, zoologist and evolutionary thinker, widely respected in his time as one of the originators of the idea of evolution and the founder of modern biology and comparative anatomy. He spent his career at the Muséum national d'Histoire naturelle, Paris. His enormous treatise on fossils included a volume on cetaceans, and he carried out many basic studies of cetacean anatomy, including the first description of the inner ear, and compiled one of the first stranding reports (1812).

Cuvier, G. (1817 and subsequent editions). "Le Règne Animal distribué d'après son organisaton, pour servir de base a l'histoire naturelle des animaux et d'introduction à l'Anatomie Comparée." Deterville, Paris.

Cuvier, G. (1821–1825). "Recherches sur les ossemens fossiles, òu l'on rétablit les caractères des plusiers animaux dont les révolutions du globe ont détruit les espèces." Second ed., 10 vol. (Vol. 5, on Cetacea; 1823). Dufour and d'Ocagne, Paris.

Dawbin, William H. (1921–1998) New Zealand-born biologist, historian and teacher who pioneered much of the early research on distribution and movements of humpback whales and right whales in the Southern Hemisphere. He was launched into marine mammalogy by early years spent in the whaling grounds of the Southern Ocean. His later work focused on catch history of whales in the Southern Hemisphere. He was also a noted herpetologist.

Dawbin, W. H. (1956). The migrations of humpback whales which pass the New Zealand coast. *Trans. Roy. Soc. NZ* **84**, 147–196.

Dawbin, W. H. (1986). Right whales caught in waters around south eastern Australia and New Zealand during the nineteenth and early twentieth centuries. *Rep. Int. Whal. Comm. (Spec. Iss.)***10**, 261–267.

Dawbin, W. H. (1997). Temporal segregation of humpback whales during migration in southern hemisphere waters. *Mem. Queensland Mus.* **42**, 105–138.

Eschricht, Daniel Frederick (1798–1863) A pioneer in many aspects of modern cetology: the first to consider cetaceans, including harbor porpoises, narwhals and belugas, as migrating animals; the first to describe the embryo of a whale based on dissections; the first to distinguish between the bowhead and right whales; the first (with Owen) to see concentric layers of growth in the teeth of cetaceans; and the first to identify different populations of killer whales in the Arctic. Most of his work was in Danish and largely inaccessible to other marine mammal scientists until published in English by Flower (1866). The gray whale, *Eschrichtius robustus*, bears his name.

Eschricht, D. F. (1840–1842). Om undersögelsen of de nordiske Hvaler. *Skand. Naturf. Förhandl.* **2**, 83–108, 203–227.

Flower, W. H. (Ed.) (1866). "Recent Memoirs on the Cetacea by Professors Eschricht, Reinhardt and Lilljeborg." For Ray Society by Hardwicke, London.

Fay, Francis H. (1927–1994) Born in Massachusetts and spending most of his career at the University of Alaska, "Bud" Fay was the world's leading expert on the walrus. He translated and made accessible to western scientists much of the massive Russian literature on marine mammals of the North Pacific and Arctic.

Fay, F. H. (1982). Ecology and biology of the Pacific walrus, *Odobenus rosmarus divergens* Illiger. *N. Am. Fauna* **74**, 1–279.

Fay, F. H. (1997). Status of the Pacific walrus population, 1950–1989. *Mar. Mamm. Sci.* **13**, 537–565.

Flower, William Henry (1831–1899) Gray's student and his successor as curator of the huge collection of marine mammal specimens at the British Museum in the last quarter of the 18th century, Flower was an extremely able zoologist who contributed major works on the beaked whales and the delphinid cetaceans, as well as publications on manatees and pinnipeds.

Flower, W. H. (1871). On the recent ziphioid whales, with a description of the skeleton of *Berardius arnuxi*. *Trans. Zool. Soc. London* **8**, 203–234, pl. 27–29.

Flower, W. H. (1884). On the characters and divisions of the family Delphinidae. *Proc. Zool. Soc. London* **1883**, 466–513.

Fraas, Eberhardt (1862–1915) German paleontologist, one of the first to study the oldest Eocene whales, e.g., *Protocetus*.

Fraas, E. (1904). Neue Zeuglodonten aus dem untern Mitteleozan van Mkattam bei Cairo. *Geol. Palaeot. Abhandl. Jena* **6 (3)**. 199–220.

Fraser, Francis C. CBE, FRS (1903–1978) The main practioner of British cetology in the mid-20th century, which was far ahead of its state in North America. A Scot by birth, he was Keeper of Zoology in charge of the whales, dolphins and porpoises at the British Museum for several decades. A UK-wide stranding program had started early in the century (stranded animals are "royal fish" and property of the sovereign), and Fraser kept it going and authored elaborate periodic reports up into the 1970s. His classic work with Peter E. Purves on the comparative functional morphology of the cetacean ear resulted in a classification that has endured and proved to be largely consonant with phylogenies generated by the most modern methods. He described Fraser's dolphin, *Lagenodelphis hosei*, from a skeleton that had languished in the BM collection for over 50 years as an "abnormal" or hybrid specimen. Much of today's cetology is built on his work.

Fraser, F. C. (1956). A new Sarawak dolphin. *Sarawak Mus. J.* **7**, 478–503. pl. 22–26.

Fraser, F. C. (1960). Hearing in cetaceans. Evolution of the accessory air sacs and the structure and function of the outer and middle ear in Recent cetaceans. *Bull. Brit. Mus. (Nat. Hist.), Zool.* **7**, 1–140, 53 pl.

Fraser, F. C. (1974). "Report on Cetacea stranded on the British Coasts from 1948 to 1966." British Museum (Natural History), London.

Gaskin, David E. (1939–1998) British biologist; started out as a lepidopterist (and remained one), but a stint as a biologist on a UK whaling ship in the Antarctic steered him into whale biology and led him to extensive work on the cetaceans of New Zealand and the porpoises of the North Atlantic. For many years, his book on the ecology of whales and dolphins was the only textbook available to teachers of marine mammalogy.

Gaskin, D. E. (1968). The New Zealand Cetacea. *N.Z. Mar. Dept Fish. Res. Bull. (New Series)* **1**, 1–92.

Gaskin, D. E. (1982). "The Ecology of Whales and Dolphins." Heinemann, London.

Gaskin, D. E. (1992). Status of the harbour porpoise, *Phocoena phocoena*, in Canada. *Can. Field-Nat.* **106**, 36–54.

Gervais, Paul François Louis (1816–1879) French zoologist and paleontologist; he described several cetacean species, explored the anatomy and reproduction of dolphins and whales, and collaborated with Van Beneden to produce the classic atlas of cetacean osteology that is still in use today. (See also VAN BENEDEN).

Gervais, P. (1853). Description de quelques espèces de phoques et de Cétacés. *Ann. Sci. Nat.* **20**, 281–292.

Gervais, P. (1856). Sur trois espèces de dauphins qui vivent dans la région du Haut Amazone. *Comp. Rend. Acad. Sci.* **42**, 806–808.

Gray, John Edward (1800–1875) Had a plan as a young man to "form the largest and most complete Zoological Collection known" and he succeeded, being personally responsible for the building of the huge collections of the British Museum amassed during the Victorian period of wide zoological exploration. He worked and published prolifically on nearly every animal group. To keep track of the current literature, he started the Zoological Record. Among his 1096 publications (1820–1875) were scores on whales, dolphins, porpoises, seals, otters and other aquatic mammals. We still recognize sixteen of the marine mammal species he described (three pinnipeds, one baleen whale, two toothed whales, and ten dolphins and small toothed whales), as well as many of his higher taxa. *Mesoplodon grayi* is named after him.

Gray, J. E. (1866). "Catalog of Seals and Whales in the British Museum." Second Edition. British Museum, London.

Gray, J. E. (1870). The geographical distribution of the Cetacea. *Ann. Mag. Nat. Hist., Ser. 4*, **6**, 387–394.

Gulland, John FRS (1926–1990) Eminent English fisheries mathematician and teacher who was a member of the independent committee of scientists commissioned in the 1960s to assess the status of Antarctic whale stocks; the committee predicted collapse of the stocks due to commercial over-exploitation, and that came to pass. He was the mainstay of the fisheries department of the Food and Agriculture Organization (FAO) of the UN in Rome for nearly 20 years, running highly effective training courses in developing countries around the world, and authored several important texts on fishery assessment and management.

Gulland, J. (1965). The plight of the whales. *Oryx* **8(2)**:74–98.

Gulland, J. (1972). The conservation of Antarctic whales. *Biol. Cons.* **4**, 335–344.

Gulland, J. (1983). "Fish Stock Assessment: A Manual of Basic Methods." J. Wiley and Sons, New York.

Harrison, Sir Richard J. FRS (1920–1999) English anatomist and functional morphologist who first made his mark in human anatomy and medicine. He became deeply interested and intrigued by marine mammals through discussions with Francis Fraser of the British Museum and went on to produce landmark works on the reproduction and general biology of whales, dolphins and seals. He received a knighthood for his contributions to marine biology, education and public service.

Harrison, R., and King, J. E. (1965). "Marine Mammals." Hutchinson Univ. Library, London.

Harrison, R. J. (Ed.). (1972–1977). "Functional Anatomy of Marine Mammals," Vol. 1–3. Academic Press, London.

Ridgway, S. H., and Harrison, R. J. (1981–1999). "Handbook of Marine Mammals," Vol. 1–6. Academic Press, San Diego and London.

Harrison Matthews, Leonard FRS (1901–1986) An early participant in the British *Discovery* investigations in the Antarctic; authored basic monographs on the elephant seal, humpback whale, sperm whale and sei whale. Much of his research focused on growth and reproduction. In later life he wrote several semi-popular books on marine mammals and antarctic research.

Harrison Matthews, L. (1937). The sperm whale, *Physeter catodon*. *Discovery Rep.* **17**, 93–168, pl. 3–11.

Harrison Matthews, L. (1952). "Sea Elephant—The Life and Death of the Elephant Seal." Macgibbon and Kee, London.

Harrison Matthews, L. (1978). "The Natural History of the Whale." Colombia Univ. Press, New York.

Hershkovitz, Phillip (1909–1997) Known mainly for his voluminous works on the systematics and ecology of neotropical terrestrial mammals, Hershkovitz turned to cetaceans at one point and produced his classic *Catalog of Living Whales*, a definitive reference indispensible to any cetacean systematist. While many of his taxonomic "calls" subsequently have been second-guessed, he led the way for cetologists in the last half of the 20th century.

Hershkovitz, P. (1966). Catalog of living whales. *U. S. Nat. Mus. Bull.* **246**, 1–257.

Hubbs, Carl L. (1894–1979) A polymath naturalist born in Arizona whose career and publications spanned over 65 years and included the study of fishes, birds, marine mammals, archeology, geochronology, geology, climatology, evolution, hybridism and the practice of systematics. He carried out the first aerial surveys of gray whales, re-discovered the supposedly extinct Guadaloupe and Juan Fernandez fur seals, and was a major force for the conservation of marine animals and their habitats. He persuaded the Mexican Government to establish the first gray whale sanctuary, in Scammon's Lagoon. Hubb's beaked whale, *Mesoplodon carlhubbsi*, was named in his honor; he and other faculty members at the Scripps Institution of Oceanography ate the type specimen during World War II meat rationing (the osteological portions fortunately were saved).

Hubbs, C. L. (1946). First records of two beaked whales, *Mesoplodon bowdoini* and *Ziphius cavirostris*, from the Pacific coast of the United States. *J. Mamm.* **27**, 242–255.

Hubbs, C. L., and Hubbs, L. C. (1967). Gray whale censuses by airplane in Mexico. *Calif. Fish Game* **53**, 23–27.

Ichihara, Tadayoshi (1939–1981) Japanese marine mammalogist known for his description of the pygmy blue whale, *Balaenoptera musculus brevicauda*, and for pioneer research on the telemetry of marine animals, including dolphins and seals. This innovative worker did much in his too-brief career to inject rigor and modern technology into Japanese marine mammalogy.

Ichihara, T. (1957). An application of linear discriminant function to external measurements of fin whale. *Sci. Rep. Whales Res. Inst., Tokyo* **12**, 127–189.

Jonsgård, Åge (1916–1997) Norwegian whale biologist and professor who carried out classical studies on the minke and fin whales and was an influential member of the Scientific Committee of the International Whaling Commission.

Jonsgård, Å. (1951). Studies on the little piked whale or minke whale (*Balaenoptera acutorostrata* Lacépède). Report on Norwegian investigations carried out in the years 1943–1950. *Norsk Hval.-Tid.* **40**, 209–232.

Jonsgård, Å. (1966). Biology of the North Atlantic fin whale *Balaenoptera physalus* (L.). Taxonomy, distribution, migration and food. *Hval. Skr.* **49**, 1–62, fig. 1, map.

Kellogg, Remington (1892–1969) Paleontologist, mammalogist and popularizer of cetaceans at the Smithsonian Institution. He produced dozens of works on fossil whales, dolphins, porpoises and seals, including the classic and massive "Review of the Archeoceti." His doctoral thesis "History of Whales—Their Adaptations to Life in the Water" has served as a primer for cetologists for generations. He took part in the early stages of the organization of international agreements on whaling beginning in the 1930s. The first U.S. Commissioner to the IWC, he battled vigorously but unsuccessfully in the 1960s for limitation of commercial exploitation of whales to sustainable levels. Although he did not win the day, the heat of the controversy led to later independent review of the whale stocks and eventual effective regulation of whaling.

Kleinenberg, Sergei Evgenyevich (1909–1968) Russian biologist who studied mammals in the field and laboratory; published extensively on the dolphins and porpoises of the Black Sea and, with three colleagues, produced a monograph on the beluga that has been the basis of all subsequent studies of the species. With his student G. A. Klevezal', he contributed greatly to development of the methodology of determining age in mammals through the examinations of layers in hard tissues.

Lacépède (Bernard Germain Etienne de Laville-sur-Ilon, Compte de Lacépède) (1756–1826) French zoologist who was one of the first modern zoologists to critically review the cetaceans. Colored plates from his book were extensively copied in other authors' works of the 19th century. He listed 34 species in the first edition (more in later editions), many more than any previous worker. Working with the collections in the Muséum National d'Histoire Naturelle, Paris, beginning in 1784, he was highly honored in his time and worked successfully under the monarchy, the republic, the empire and the new monarchy.

Leatherwood, J. Stephen (1944–1997) Marine mammalogist, naturalist, and conservationist, born in Alabama. He authored or coauthored a series of widely used identification guides and guided the establishment of marine mammal research and conservation programs in many of the less-developed nations in Latin America and Asia.

Linnaeus, Carolus (1707–1778) Swedish physician and avid naturalist considered the father of modern taxonomy; he worked extensively in the field with birds and plants. Linnaeus named and classified all the then known species of plants and animals in the first edition of his Systema Naturae in 1735, using his binomial system of a species name consisting of genus and trivial name. The official starting point of zoological nomenclature is 1758 (International Commission on Zoological Nomenclature—1985), the year of publication of the 10th edition of his work. In that edition, he gave us 13 species of marine mammals that are still recognized.

Mackintosh, Neil A. (1900–1974) British biological oceanographer and authority on Antarctic whales; his contributions were massive. He was one of the prime organizers of the Discovery investigations that have contributed much to the knowledge of marine mammals and ecology of the Southern Ocean. He authored landmark monographs on whales, plankton and ice, edited and shepherded the Discovery Reports, launched the international whale-marking scheme, was instrumental in the founding of the British Antarctic Survey, and was a leading player in (and first chairman of the Scientific Committee of) the IWC.

Mackintosh, N. A. (1965). "The Stocks of Whales." Fishing News (Books), London.

Nemoto, Takahisa (1930–1990) The major authority on the plankton consumed by whales; born in Tokyo and carried out his studies at the Whales Research Institute (1953–1977) and Ocean Research Institute of University of Tokyo (1977–1990). He was instrumental in the organization of the international project BIOMASS to study the ecology of the Southern Ocean.

Nishiwaki, Masaharu (1915–1984) A "force of nature" for the study and conservation of marine mammals in Asia. After serving as a fighter pilot in WWII, he spent several seasons with the Japanese whaling factoryship fleet in the Antarctic; this set the direction of his career. He made basic contributions to knowledge of systematics, life history and reproduction of whales, dolphins and seals and effectively promoted conservation of cetaceans and sirenians in Japan, China, Bangladesh, India, Pakistan, Nepal, Indonesia, Russia and several nations in West Africa. He campaigned against overexploitation of whales and dolphins in Japan; his was a lone voice at the time.

Norris, Kenneth S. (1924–1998) The virtual founder of modern cetology in the United States; born in Los Angeles. He organized and chaired the first international conference on cetaceans in 1963 in Washington, D.C. Scientist, teacher and natural historian, he co-founded the Society for Marine Mammalogy and served as its first president. With William McFarland, he described the vaquita, *Phocoena sinus*, from the Gulf of California in 1958. He demonstrated echolocation in dolphins, developed theories of hearing and sound production in dolphins and the sperm whale, and carried out extensive innovative research on dolphin behavior and ecology. Also an active "biopolitician," he was influential in development of the landmark U.S. Marine Mammal Protection Act of 1972.

Norris, K. S., Prescott, J. H., Asa-Dorian, P. V., and Perkins, P. (1961). An experimental demonstration of echolocation behavior in the porpoise, *Tursiops truncatus* (Montagu). *Biol. Bull.* **120**, 163–176.

Omura, Hideo (1906–1993) Considered the dean of Japanese cetology; published detailed monographs on the osteology, systematics and distribution of baleen whales in Japanese waters and from around the world. He served for decades as Director of the industry-sponsored Whales Research Institute in Tokyo, which fostered and published the bulk of the Japanese research on cetaceans from after World War II until the late 1980s.

Poulter, Thomas C. (1897–1978) U.S. bioacoustician who worked extensively in the Arctic and Antarctic. He long advocated the idea that pinnipeds, like odontocete cetaceans, use echolocation; this was eventually discounted (see Schusterman, 1967). He is most remembered for organizing a series of conferences on biological sonar and diving mammals in the 1960s and 1970s at Stanford Research Institute; these were the forerunners of the current Biennial Conferences on the Biology of Marine Mammals.

Poulter, T. C. (1963). Sonar signals of the sea lion. *Science* **139**, 753–755.

Scammon, Charles M. (1825–1911) American whaling captain and naturalist who published only one book and one technical paper, but greatly influenced cetology and the history of whaling. He discovered the breeding grounds of the gray whale in Laguna Ojo de Liebre (also called Scammon's Lagoon) in Baja California in 1855, which led to the near-extinction of the species in the eastern Pacific. His book (rare and valuable in the original edition) is a detailed chronicle of American whaling and description of the marine mammals of the west coast of North America.

Scammon, C. M. (1869). On the cetaceans of the western coast of North America. *Proc. Acad. Nat. Sci. Philadelphia* **1869**, 13–63.

Scammon, C. M. (1874). "The Marine Mammals of the North-western Coast of North America Described and Illustrated together with an Account of the American Whale-fishery." John H. Carmany, San Francisco. (Reprinted 1968, Dover, New York).

Schevill, William E. (1906–1994) Pioneering bioacoustician who was born in Brooklyn and spent most of his career at Harvard. He made the first recordings of underwater cetacean sounds in the wild and recorded and described sounds of many species. He published the first phonograph record of cetacean sounds. With wife and research partner Barbara Lawrence he described the anatomy of the delphinid nasal passages functional in sound production.

Schevill, W. E., and Lawrence, B. (1950). Underwater listening to the white porpoise (*Delphinapterus leucas*). *Science* **109**, 143–144.

Scholander, Per F. ("Pete") (1905–1980) Norwegian-born physiologist who made many basic discoveries and advances in the respiratory physiology and ecology of diving mammals, including observation of the slowing of heart rate (the "diving response") in submerged seals and description of countercurrent heat-exchange structures in the dorsal fin and flukes of cetaceans. He pioneered direct physiological monitoring and experimentation with captive live marine mammals to explore their respiratory and cardiovascular adaptations.

Scholander, P. F. (1940). Experimental investigations on the respiratory function in diving mammals and birds. *Hvalråd. Skr.* **22**, 1–131.

Scoresby, William (1789–1857) Born in Yorkshire, England: accompanied his father on a whaling expedition when he was ten years old, an event that shaped his life; he published his first paper on whales at the age of 19. His most important work "An Account of the Arctic Regions and Description of the Northern Whale Fishery" is the best contemporary account of the Arctic and whaling as it existed in the early nineteenth century. Several equally important books followed.

Scoresby, W. (1808). Account of the *Balaena mysticetus* or great northern or Greenland whale. *Edinb. Mem. Wern. Soc.* **1**, 578–586.

Slijper, Everhard Johannes (1907–1968) Like many cetologists of the first half of the 20th century, E. J. Slijper, the Dutch functional anatomist and student of whales and whaling, had his first experience with whale biology on a whaling expedition to the Antarctic. He authored "Walwissen" (1958), which became the famous book "Whales" in English. He analyzed reproduction, locomotion and other functions in cetaceans and other mammals with a comparative anatomical approach that became standard in such studies.

Sokolov, Vladimir Evgenyevich (1928–1998) An important figure in Russian mammalogy and member of the National Academy of Sciences of the USSR, V. E. Sokolov was a specialist on the microanatomy of the skin. He co-authored a three-volume work on the mammals of the Soviet Union, including a volume on seals and the toothed cetaceans.

Sokolov, V. E. (1962). Adaptations of the mammalian skin to the aquatic mode of life. *Nature* **195**, 464–466.

Steller, Georg W. (1709–1746) German-born botanist who in his relatively short life spent years in the wilds of the Russian Far East with the Great Siberian Expedition and collected specimens and detailed accounts of many new animals, including the Steller sea lion and the extinct Steller's sea cow of Bering Island.

Steller, G. W. (1751). "De Bestiis Marinus." St. Petersburg Acad. Sci. (posthumous; published in translation as *Von Sonderbaren Meerthieren*, Kummel, Halle, Germany, 1753).

Tomilin, Avenir Grigoryevich (1912–2000) Grand old man of Russian cetology who began his 66-year career with a season with the whaling expedition "Aleut" in the Kamchatka, Bering, and Chukchi Seas in 1934. The most famous of his hundreds of technical and semi-popular contributions is the massive volume on Cetacea in the series "Mammals of the U.S.S.R. and Adjacent Countries" (1957), which has been translated into English. Tomilin followed a lifelong commitment to popular scientific education, and his books were read by millions.

True, Frederick W. (1858–1914) The dominant figure in American cetology at the turn of the century; built the marine mammal collection of the U.S. National Museum into the second-largest in the world, after that of the British Museum. Highly prolific, he documented the American dolphin fisheries in New Jersey and North Carolina and produced scores of reports on the systematics of cetaceans, pinnipeds and other mammals, describing many new species and including the important monographic "Review of the family Delphinidae," which largely delineated the array of dolphin species recognized today, and "Whalebone whales of the North Atlantic."

True, F. W. (1889). Contributions to the natural history of the cetaceans, a review of the family Delphinidae. *Bull. U. S. Nat. Mus.* **36**, 1–191, pl. 1–47.

True, F. W. (1904). The whalebone whales of the North Atlantic. *Smithson. Contrib. Knowledge* **33**, 1–551, pl. 1–50.

Van Beneden, Pierre Joseph (1809–1894) Belgian paleontologist and morphologist of the latter half of the 19th century; he provided some of the first accurate descriptions of fossil whales. With Paul Gervais, he authored a monumental classic work on the osteology of living and fossil cetaceans that is consulted even today by cetologists seeking accurate depictions of dolphin and whale skulls and skeletons.

Van Beneden, P. J. (1864). Recherches sur les ossements provenant du Crag d'Anvers. Les Squalodons. *Acad. roy. Belg.* **2 April 1864**, 1–85, pl. 1–4.

van Utrecht, Willem Lodewijk (1926–1994) Dutch zoologist who was an important early worker in the study of age and growth structures in both toothed cetaceans and baleen whales, working with teeth in the former and both ear plugs and baleen plates in the latter. He turned to the study of aging of fishes in his later years. Much of his research was in collaboration with his wife Clara N. van Utrecht-Cock.

Winn, Howard E. (1926–1995) Oceanographer, whale biologist, and teacher who carried out some of the first acoustic studies of whale songs. He organized and headed the massive Cetacean and Turtle Assessment Program (CETAP), 1978–1982, which provided first estimates of distribution and abundance of whales, dolphins, and porpoises off the eastern U.S., and was active in conservation of the right whale in the North Atlantic.

GLOSSARY

The following section provides definitions for a list of terms that appear in the text of this Encyclopedia. For the most part these are specialized technical terms used in the field of marine mammalogy that are likely to be unfamiliar to a lay reader. Also included are terms that, though likely to be known in their common sense, have a distinctive or highly specific use in marine mammalogy.

A

abduction The movement or position of a limb away from the midline of the body.

abuse In the context of human interaction with marine mammals, a term for mistreatment involving violence that may result in injuries or death.

accessory denticles Cusps on archaeocete teeth that are not clearly homologous with primitive mammalian tooth cusps.

accidental reinforcement Another term for ADVENTITIOUS REINFORCEMENT.

acetabulum A depression in the pelvis in which the head of the femur is secured.

acoustic harassment device (AHD) A sound-generating device that, because of some combination of intensity, frequency, or other sound characteristic(s), is aversive to marine mammals and keeps or drives them away from an area or structure.

adduction The movement or position of a limb toward the midline of the body.

adenohypophysis A glandular structure, also known as the anterior pituitary, located at the base of the hypothalamus in the brain and producing a variety of hormones primarily responsible for stimulating the function of other endocrine glands.

adenosine triphosphate (ATP) A high-energy compound that, when split by enzymic activity, releases energy in the reaction.

adipocyte A cell of adipose tissue that stores fat.

advanced See DERIVED.

adventitious reinforcement Reinforcement that happens to coincide with a particular response even though that particular response was not responsible for delivery of the reinforcement. In effect, the "wrong" behavior is modified. Also, ACCIDENTAL REINFORCEMENT.

aerial behavior Any behavior that takes the animal partly or completely out of the water, e.g., lobtails, breaches, spyhops, head, side or back slaps, leaps, flips, and spins.

aerobic Pertaining to activity or metabolism in which oxygen is the final electron acceptor in the breakdown of glucose. This process produces 39 ATPs from 1 mole of glucose.

aerobic dive limit The maximum length of a dive accomplished using mainly aerobic metabolic pathways, and with no net production of anaerobic metabolites.

aggregation A term for a group of individuals that come together because of a common resource, such as a predator-free habitat, rather than by social attraction.

aggressive behavior or **aggression** A set of social interactions ranging from threats to open fights, reflecting a conflict of interest over limited resources and having the potential to cause injuries and sometimes death to participants. Generally refers to conflict involving members of the same species, but may refer to any interaction of this kind.

agonistic behavior See AGGRESSION.

agviq Northern Alaskan Inuit term for a bowhead whale.

air gun In this context, a device that releases a burst of high-pressure air into the water. Groups ("arrays") of air guns are used by the marine seismic industry to create low-frequency, high-level sound pulses that can characterize rock formations below the seafloor.

aiviq Northern Alaskan Inuit term for a walrus.

aldosterone Steroid hormone released by the adrenal gland that increases Na^+ retention in the distal convoluted tubule and the collecting duct of the kidney.

algae A general term for various small aquatic organisms, usually single-celled, which can synthesize organic matter from carbon dioxide using the energy of sunlight and whose reproductive organs are contained in a single cell. Two groups of algae, diatoms and dinoflagellates, form the basis for all other life in the sea.

allantois Fetal membrane developing from the hindgut or yolk sac that often contributes to the formation of the umbilical cord and placenta in mammals.

Allee effect A form of density dependence in which the population growth rate slows at smaller population sizes, due to factors such as the difficulty of finding suitable mates. (First described by W. C. *Allee*, 1931)

alleles Alternative forms of a gene, e.g., *W* vs. *w*; Mendel studied pea genes for Wrinkled vs. smooth seeds.

allomaternal care Care provided to offspring by individuals other than the mother.

alloparenting Parental behavior by an animal (male or female) shown toward an offspring that is not its own.

allopatric Describing taxa, species, or populations whose ranges are physically separated.

allopatry The fact of having separate, nonadjacent geographic ranges.

allozygous Describing alleles that are identical by state but not descent.

allozyme A variant form of an enzyme, differing in amino acid sequence.

alternating carpus and tarsus An arrangement of the carpal and tarsal bones in an alternate way, in the manner of bricks in a wall. This is the primitive condition for mammals as seen from various Mesozoic mammalian groups. Cf. SERIAL CARPUS AND TARSUS.

altricial Being born in a helpless state and depending heavily on adult care. In contrast, precocial young are born in an advanced state of maturation and require relatively little adult care.

ambergris A grayish waxy substance formed in the intestines of sperm whales; once widely used in perfumes.

amniote An air-breathing vertebrate with cleidoic eggs having amniotic membranes, which can be laid outside water; i.e., the nonamphibian tetrapods comprising reptiles, birds, and mammals.

amphibious Able to move, feed, and so on, both on land and in water.

amphipod A crustacean of the order Amphipoda, including those on the ocean bottom, fed on by gray whales.

anadromous Describing the migratory behavior of fish that spend most of their lives in the sea, but that then migrate to freshwater to spawn (e.g., salmon).

anaerobic Relating to activity or metabolism in which the breakdown of glucose occurs in the absence of oxygen.

anaerobic dive A dive during which enough of the required metabolic energy comes from anaerobic pathways to result in net production of anaerobic end products.

anaerobic metabolism Chemical processes that temporarily sustain life in the absence of oxygen.

anal canal The terminal specialized portion of the gastrointestinal system.

ancestral species The species from which a present species has evolved.

anestrus The period of quiescence between two periods of sexual receptivity in cyclically breeding mammals.

anlage *plural*, **anlagen** Undifferentiated embryonic cells or tissue from which an organ or part develops; primordium.

annual pregnancy rate The proportion of sexually mature females that are pregnant during any given year, adjusted for the length of the gestation period.

antecedent In operant conditioning, a stimulus (signal or cue) that precedes a behavior emitted by the animal.

anterior Toward the front or head of the body.

anterior pituitary Another term for ADENOHYPOPHYSIS.

anthropogenic Describing a phenomenon or condition created, directly or indirectly, as a result of human activity.

antidiuretic hormone Another term for VASOPRESSIN.

antilipolytic Inhibiting the breakdown of lipids.

antitropical Occupying temperate and/or colder waters in the Northern and Southern Hemispheres, but absent from the intervening tropical latitudes; having distributions north and south of the equator but not in equatorial regions.

apnea A respiratory pause; elapsed time between inspiration and expiration.

apneustic breathing A method of breathing in which the animal rapidly exhales and inhales and then holds its breath for an interval before repeating. This pattern facilitates rapid air exchange while swimming rapidly.

aponeurosis A broad tendon, connecting muscle to muscle or muscle to bone.

appendicular skeleton Bony elements of the limbs.

aquatic Having to do with water; living in or situated in water, which can be either fresh water or the sea.

Archaeoceti (archaeocetes) The suborder of whales that includes the first Cetacea to enter the sea and all their descendants that do not have cranial telescoping.

Arctoidea A phylogenetic grouping that includes the Ursidae (the bear family), Pinnipedia (seals, sea lions, and walruses), Procyonidae (the raccoon family), and Mustelidae (weasels, badgers, otters, and skunks) and that is the sister group to the Cynoidea (the dog family).

arteriovenous anastomoses Vascular shunts between the arterioles and venules in blubber near the body surface.

artificial insemination The introduction of semen into the vagina, cervix, or uterus by artificial means in an attempt to cause conception.

Artiodactyla Even-toed hoofed mammals; the mammalian order that includes hippopotamuses, pigs, peccaries, camels, chevrotains, cattle, antelopes, deer, and giraffes. Among living mammals, probably the closest relatives of whales.

asphyxia A combination of decreased oxygen (hypoxia), increased carbon dioxide (hypercapnia), and the accumulation of acidic metabolic by-products (acidosis).

assemblage A predictable and particular collection of species within a biogeographic unit.

assortative mating Nonrandom mating in which members of a population pair up with individuals who are either more (positive) or less (negative) like themselves than the average for one or more traits.

atavistic Referring to the reappearance of a characteristic or feature in an individual belonging to a lineage whose members have secondarily lost that characteristic.

audiogram A hearing sensitivity curve drawn as a function of frequency.

auditory bulla The ear bone in odontocetes that houses the inner ear structure.

auditory meatus An opening to the ear.

autosomal chromosomes A collective term for all the nuclear chromosomes except the sex chromosomes.

autozygous Describing alleles that are identical by state and descent.

axial skeleton The bony elements of the body, excluding the limbs.

B

bachelor school A term for an apparently loose aggregation of mature or maturing male sperm whales, usually consisting of animals of similar ages.

backdown procedure A procedure used to release dolphins from the purse seine by pulling on the net after it has been pursed.

baleen Plates of dense, hair-like material (keratin) that hang side by side in rows from the roof of the mouth of whales in the order Mysticeti (the baleen whales); forming the "baleen apparatus" for filter feeding on surface plankton. Formerly known as "whalebone" but bearing no actual resemblance to true bone.

barnacles A collective name for various marine crustaceans of the subclass Cirripedia; the adults form a hard outer shell and attach to underwater surfaces such as rocks and ships, as well as to certain whales.

barrage In this context, a low gated dam used to divert water for irrigation, flood control, and/or navigation purposes. Normally the gates remain closed during the low-water season and are opened during the high-water season with differing levels of regulation in between.

basal insectivores Plesiomorphic representatives of Insectivora (hedgehogs, shrews, moles, etc.). They can be used as a theoretical basis for the calculation of encephalization and size indices and for the derivation of more progressive insectivores and other eutherian mammals.

basal metabolic rate The metabolic rate for a adult animal resting within its thermoneutral zone without food in its gut.

basicranial anatomy The base of the skull, particularly the size and shape of bones contributing to the auditory bulla; this has proven to be very important for interpreting phylogenetic relationships within Carnivora.

Bayesian Referring to a method of drawing inference about unknown parameters in which parameters are assigned a prior distribution independent of data and a posterior distribution given the data is calculated. (From Thomas Bayes, 1702-1761, English mathematician.)

beak In cetaceans, a term for the elongated anterior portion of the skull that includes both the upper jaw and the lower jaw.

beaked whales Members of the family Ziphiidae, which includes five current genera: Berardius, Hyperoodon, Mesoplodon, Tasmacetus and Ziphius.

behavior An observable and measurable event performed by an organism. Can also include nonobservable phenomena (such as emotion, cognition, recall) that can be measurable through other assessment strategies.

behavioral adaptation An animal's ability to learn to discern dangerous from nondangerous stimuli, and to react accordingly upon subsequent encounters.

behavioral ecology The influence of the environment on behavior.

behavior medicine Training programs and behavioral procedures intended to specifically condition behaviors that treat or prevent health disorders.

bellyflop A term for a breach in which the animal lands ventrally, on its stomach.

benthic Living in or on the ocean floor.

bicipital groove A groove on the humerus through which a tendon of the biceps muscle runs.

binocular vision The fact of seeing an object with two eyes simultaneously, as in humans. Necessary (but not sufficient) for stereoscopic vision.

binomial name The scientific Latin name of a species, consisting of two parts: the generic name and the trivial name. Note that the trivial name is not the "species names;" two species can have the same trivial name (e.g., the cetaceans *Stenella attenuata* and *Feresa attenuata*), but each has a unique, two-part species name.

biodiversity The diversity of species; a term variously defined but generally construed to mean the relative abundance of different species (and their population size) within a given area, or on Earth as a whole.

bioluminescence Light emitted by certain marine organisms as the result of a chemical reaction; this may be used to avoid or confuse predators, to attract prey, or to attract mates.

biomarker A biological response to a chemical that gives a measure of exposure and sometimes a toxic effect.

biomass A measure of the amount of plant or animal matter in a given context or system, expressed in terms of its aggregate weight.

bipolar Living or found in both polar regions.

blow A term for a cloud of vapor and sea water mixed with air that is exhaled by cetaceans.

blowhole The external opening of a whale's ventilatory system. Two blowholes occur in baleen whales and one in toothed whales.

blue whale unit (BWU) A measure of baleen whale harvest that reflects oil production. One BWU is equivalent to a blue whale, 2 fin whales, 2.5 humpback whales, or 6 sei whales.

blubber A specialized layer of fat that functions as an insulator, found between the skin and underlying muscle of most marine mammals.

bow-riding The action or behavior pattern of riding on the pressure wave in front of the bow of a ship.

bradycardia A condition of decreased heart rate.

brainstem-evoked potential Electrical nervous discharges generated by an external stimulus in a sensory system.

branchial arches Embryonic precursors of mammalian jaw, ear, face, and throat structures that are derived from elements homologous to the gill arches of fish.

breach or breaching A cetacean behavior in which the animal leaps out of the water and reenters on its side or back, often creating a large splash.

breeding sites Traditional land areas (mostly beaches) where adult females give birth and adult males defend territory.

bridging stimulus A conditioned stimulus that signals the imminent delivery of reinforcement.

brine channels Small pockets of brine in seawater ice that have a lower freezing point than the rest of the ice and often remain liquid.

bristles The fine fringe on the inner side of baleen plates that mats to form a sieve for food.

bristle worm A marine worm with short legs.

bunolophodont Referring to a molar having rounded (bunodont) cusps that are joined to form crests (lophs).

buoyancy Upward force exerted on a swimmer's body when it is immersed or floating in water.

burden of proof The duty of proving a disputed assertion. In ecology, traditionally the burden of proof has been placed on scientists to show that harm to resources will result from some human action. The precautionary principle reverses this standard to require proof that a human action will not harm the resource.

bycatch Animals that are caught accidentally in fishing operations; the capture and mortality of all organisms that are not the target species of a fishery.

C

calcareous Composed of calcium carbonate, a chemical compound similar to chalk.

calf A young animal dependent on its mother; applied to the young of cattle and also analogously to other large mammalian species, including some marine mammals.

callosity A patch of thickened, keratinized tissue on the head of a right whale, inhabited by large numbers of whale lice.

cannibalism The consumption by an animal of members of its own species.

carcinoma A cancer arising in an epithelial tissue.

cardiac Relating to or describing the portion of the stomach that lies next to the esophageal opening and contains the cardiac glands.

Carnivora An order of living and extinct mammals that includes such species as dogs, cats, bears, and seals.

carnivoran A term applied to all members of the order Carnivora, distinguishing them from other mammals that may be ecological carnivores.

carnivore An organism that feeds on live prey, in the case of marine mammals including fish and cephalopods as well as mammals, birds, and reptiles.

carnivorous Meat-eating; describes the diet of members of the order Carnivora but many other mammals as well.

carrying capacity The maximum population that can be sustained in a given ecosystem without altering the ecosystem in ways that will ultimately reduce the sustainable population.

catecholamines A class of biologically active compounds, including epinephrine (adrenalin) and norepinephrine (noradrenalin), produced by cells of the adrenal medulla and other neurological structures.

caudal Having to do with or near the tail or fluke; behind.

caudal fin The fin located on the extremity of the tail of fishes, dolphins, and so on.

caudal vertebrae Vertebrae caudal to the sacral vertebrae in most marine mammals; in cetaceans and sirenia, the vertebrae associated with chevron bones.

cecum or **caecum** A large blind pouch forming the beginning of the large intestine.

cementum A calcified tissue that fastens the roots of teeth to the teeth sockets.

centrum The center part of the vertebra.

cephalopod A member of the group of mollusks including squids, cuttlefish, and octopuses.

cervical Relating to or near the neck region.

cervical vertebrae The vertebrae of the neck.

cestode Any flatworm of the class Cestoda, including tapeworms.

Cetacea An order of living and extinct mammals that includes such species as whales, dolphins, and porpoises.

cetacean **1.** Any member of the order Cetacea of aquatic, mostly marine mammals that includes whales, dolphins, porpoises, and related forms; among other attributes they have a long tail that ends in two transverse flukes. **2.** Belonging to or describing this order.

chevron bone Any of a number of small bones positioned on the ventral aspect of the caudal intervertebral discs. These bones are common in mammalian tails, but they are particularly large in cetaceans and sirenians. In cetaceans, chevron bones are often V-shaped and they embrace the arteries that supply the tail.

chin slap A cetacean behavior pattern in which the animal raises its head out of the water and slaps it back down to make a splash.

chitin A tough insoluble polysaccharide, the main constituent of the arthropod exoskeleton.

Chordata One of the phyla (large groupings) of animals. They are characterized by the presence of a chorda (= notochord), a bar that supports the dorsal side of the animal.

choroid The thin, pigmented, vascular layer between the sclera and the retina of the eye. It consists mainly of blood vessels, which provide nourishment to the retina. The choroid also reduces internal reflection of light.

chromatophore A pigment cell or group of cells, which can be altered in shape or color in response to stimuli from the nervous system or hormones.

circadian Describing a biological rhythm with a period of approximately 24 hours.

circumpolar Distributed around the North or South Pole; in this context, referring to the distribution of species living in the cold water masses of the Southern Ocean.

clade An evolutionary line; a monophyletic group containing all the descendants of the most recent common ancestor of that group.

cladistic Based on a pattern of descent, with the most closely related (sister) taxa having a common immediate ancestor.

cladistics A method of classifiying organisms in which species are delimited in time by branching points on an evolutionary tree (speciation events), with taxa being defined solely on the basis of common ancestry.

clan In this context, killer whale pods that share parts of their vocal repertoire (related dialects), reflecting a probable common matrilineal ancestry.

classical conditioning A type of learning in which a conditioned (learned) stimulus is presented in conjunction with an unconditioned stimulus, creating a conditioned (learned) response. During classical conditioning, learning occurs independent of the ongoing activities of the organism.

clean-entry leap A term for a breach in which the animal returns to the water smoothly, head first.

click In phocoenids, a sound of small duration (microseconds) and of narrow band produced at center frequencies between 110 and 150 kHz.

cline Gradual change over a geographic range.

clupeid See CLUPIOID.

clupioid fish A member of an order of schooling marine fishes including sardines, anchovies, and herrings that are often observed in the diets of marine mammals.

coda A patterned series of 3–20 clicks lasting about 0.5–2.5 seconds, used by sperm whales for communication.

codon The sequence of three nucleotides in DNA or messenger RNA that encodes for a particular amino acid.

coefficient of variance A description of the error associated with a statistical estimation.

coelom The body cavity holding the organs.

collagen matrix A protein web that forms the structure of blubber found in marine mammals.

collecting duct The terminal segment of the mammalian nephron.

colonization Occupation or use of an area for breeding by a group of animals.

commensalism A relationship or association of organisms in which one individual benefits at no expense or damage to the other organism (the host).

community An association of interacting groups within a larger population, usually defined by the nature of their interactions or by the place in which they live.

compensation A form of density dependence in which the population growth rate slows at larger population sizes.

competition Interaction between individuals of the same species (intraspecific competition) or between different species (interspecific competition) such that the simultaneous presence of the two competitors is mutually disadvantageous. In terms of competition between humans and marine mammals, the competitive mechanism may be direct, as when a marine mammal eats a fish that could otherwise have been caught by a fisherman, or indirect, as when a marine mammal consumes a fish that is an important prey species of a commercially desirable fish species.

competitive group In this context, a group of three or more humpback whales characterized by a nuclear animal (usually female), a principal escort (male), and one or more other males, who may challenge the principal escort for his position. Competitive groups are assumed to be related to mate choice or mate defense; they are often large and sometimes involve considerable intrasexual aggression.

competitive release A phenomenon of competitive interaction that occurs when predation (natural or from increased fishing) causes a reduction in one of two groups that are in competition. The second group then increases in size as a result of this "competitive release."

computed (axial) tomography A method of using X-rays to produce visual "slices" through an object.

conditioned stimulus A stimulus that attains the ability to "cue" behaviors as a result of learning.

confidence interval In statistics, a range of values, expressed as a minimum and a maximum, in which the real value of an estimate can be placed with a desired confidence.

connecting chamber A stomach compartment in cetaceans that lies between the main and pyloric chambers; lined with pyloric epithelium.

conspecific **1.** Of an organism, belonging to the same species as another or others. **2.** An individual of the same species as another or others.

contest competition A mechanism of sexual selection in which males compete by fighting with each other to achieve exclusive access to one or more mating females and in which females typically mate with the winners of such battles.

context-specific learning Learning that occurs in an environment in which background stimuli and discrete environmental cues are required for the animal to respond correctly.

continental shelf The part of a continent that is submerged in relatively shallow sea.

continental slope The slope of the sea floor between the continental shelf and the ocean floor, which is steep and 150–4000 m deep.

convergence zone An equatorial region where two north–south currents meet, forming an east–west current.

convergent evolution The evolution by unrelated organisms of structures that are similar in appearance or function.

copepod An organism of the order Copepoda; a small crustacean.

Copepoda An order of very small planktonic crustaceans present in a wide variety and great abundance in marine habitats, forming an important basis of ecosystems.

cortex The outermost layer of tissue of an organ.

cortisol A steroid hormone of the adrenal cortex that is involved in the regulation of protein and carbohydrate metabolism.

cosmopolitan Occurring worldwide or nearly worldwide.

costal Wing-like or lateral.

cotyledon In this context, a unit of the placenta grossly visible as a lobe circumscribed by a deep cleft.

cranial Having to do with the head or nose.

cranial muscle A muscle innervated by one of the cranial nerves.

cranial nerve A nerve that leaves the central nervous system near its anterior end and enters the periphery of the body by traversing one of the foramina of the skull. There are 12 named pairs of cranial nerves in all mammals.

cranial vertex The highest point of the skull, immediately caudal to the bony external nares. The nasal, maxillary, premaxillary, and frontal bones contribute to this region.

crepuscular Having to do with or active at the margins of the day; i.e., at dawn and/or dusk.

Cretaceous A period of geological time, from about 144 million to 65 million years before the present, ending with a mass extinction.

critically endangered A term used to describe a taxon that is facing an extremely high risk of extinction in the wild in the immediate future.

critical period A period of rapid acquisition that is usually associated with early stage development.

crossbow whaling A whaling method using a harpoon that is shot from a rubber-powered crossbow instead of a cannon, originating in Okinawa in 1975 to take advantage of a loophole in whaling regulations.

crown group A clade that includes the most recent common ancestor of all living species, plus all its descendants. Examples in Cetacea: Odontoceti and Mysticeti.

crus The middle region of the hind limb, consisting of the tibia and fibula and surrounding structures.

cryopreservation A process of maintaining the viability of cells, tissues, or organs by storing them at very low subzero temperatures.

cull **1.** To remove certain individuals from a population to control the overall population. **2.** An individual removed in this manner.

culling The process of reducing the population level of a given species. Distinguished from HARVEST, which refers to taking animals for commercial purposes.

cursorial Adapted for moving quickly over land; fast-running.

cusp A point on the grinding surface of a tooth.

cutaneous Referring to the skin surface of an animal.

cyamid A term referring to whale lice, all of which belong to the family Cyamidae.

cyclonic Describing rotation in the same direction as the earth (clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere).

cytochrome b A protein involved in respiration, coded for by an 1100-bp region of the mitochondrial genome.

D

dactyli The fingers or claws on appendages of invertebrates.

deciduous dentition The first generation of teeth of a mammal that erupt early in life and are later replaced by a second generation of permanent teeth. Unlike other mammals, modern cetaceans only have one tooth generation.

deciduous tooth A tooth that will be replaced, a replacement tooth, as opposed to a permanent tooth.

deep scattering layer (DSL) Organisms associated with the edge of the light, or photic, zone in deep water. The DSL tends to migrate vertically on a daily–nightly (diel) basis, being many hundreds of meters below the surface in daytime and closer to the surface at night.

definitive host The host in which a parasite achieves sexual maturity.

delayed implantation **1.** A period of suspended development or growth. **2.** Specifically, in pinnipeds, the suspended development of an embryo between shortly after conception and subsequent attachment (implantation) to the uterine wall.

delphinid A small dolphin species belonging to the family Delphinidae.

demersal A fishing term referring to marine resources captured near the bottom.

demographic Relating to or describing population levels or characteristics.

demographics **1.** The characteristics of a biological population such as population size, proportion of reproductive females, or age at first reproduction. **2.** the study of influences on or changes in such characteristics.

demography **1.** The birth and death rates that determine a population's dynamics. **2.** See DEMOGRAPHICS.

density dependence The dependence of population growth rate on population density or size.

dental formula A numerical summary of the numbers of teeth of each class (incisor, canine, premolar, molar) in the dentition of a mammal. For example, a dog has three incisors, one canine, four premolars and two molars in the upper jaw, and three incisors, one canine, four premolars, and three molars in its lower jaw; thus its dental formula is 3.1.4.2/3.1.4.3.

dentinal growth layer group A layer of dentine, consisting of one translucent and one opaque zone when examined in the longitudinal, thin section of a tooth. The number of these growth layer groups is used to indicate the age of toothed whales.

depleted A term indicating that a species or population stock is below its optimum sustainable population level or that a species or population stock is officially listed as endangered or threatened.

depredation An act of facilitated predation, in which an animal raids or plunders something already caught or otherwise claimed by a fishery.

derived Referring to a character or structure of an organism that has been modified relative to its ancestor; an evolutionary "new" feature.

Desmostylia Extinct "seahorses," a group of herbivorous marine mammals characterized by cheek teeth consisting of clusters of enamel/dentine columns.

diaphragm A musculotendinous sheet between the pleural and peritoneal cavities of mammals; generally considered the most powerful muscle associated with breathing.

diastole The period of ventricular relaxation during the contraction–relaxation cycle of the heart.

diatoms Single-celled algae abundant in marine and freshwater environments.

diel Occurring on a 24-hour cycle.

die-off Mortality on a large scale. This may involve more than one species and can occur over days, weeks, or months.

differential reinforcement A procedure in which reinforcement occurs for any behavior other than the target behavior. The effect is to decrease the target behavior while increasing other (more appropriate) behaviors.

dimethyl sulfoxide (DMSO) A chemical compound that increases cell wall permeability.

dimorphism **1.** A difference in form (body size, shape, or color) between two individuals or two groups of individuals. **2.** see SEXUAL DIMORPHISM.

dinoflagellates Single-celled algae, which, unlike diatoms, are capable of active movement.

diphyodont Developing two successive sets of teeth.

direct fitness The gene contribution of an individual to the ensuing population through its own offspring.

dispersal **1.** The movement of an individual from its birth place to separate feeding grounds, or its integration into a different population. **2.** Any outward spreading of organisms from their point of origin.

display behavior Behavior that is evolutionarily specialized for some form of communication, such as bird song. Special structures, colors, or coat patterns commonly evolve as parts of displays.

distinct population segment A population of organisms that is discrete from the other populations of its taxon and that represents a significant (in terms of numbers or range) or ecologically unique portion of a species or subspecies.

diurnal Active during the daylight hours, while inactive or sleeping at night.

diversity **1.** See GENETIC DIVERSITY. **2.** See BIODIVERSITY.

diving response A suite of physiological and biochemical reactions that are activated when a marine mammal dives, in order to conserve oxygen and extend dive time.

dolphin Any of the small cetaceans in the families Delphinidae (under about 3–4 m in length), Iniidae, Pontoporiidae, Lipotidae and Platanistidae.

dolphin-assisted therapy The use of dolphins to assist in the treatment of such human disorders as depression, autism, cerebral palsy, or mental retardation.

Doppler shift A change in frequency due to the relative motion of a transmitter and observer.

dorsal Toward or relatively near the back and corresponding surface of the head, neck, and tail.

dorsal cape A region of solid color extending along the forward dorsal surface of a dolphin and sweeping up behind the dorsal fin.

dorsal fin The fin on the top midline of the body, as in dolphins.

dorsoventral From top to bottom.

drag The physical force resisting the movement of a body or limb through water or another fluid medium.

drive fishery A style of fishing for dolphins in which speedboats are used to corral a school of dolphins into a bay or shallow water. A net is drawn across the mouth of the bay or around the school, which prevents their escape. The fishermen then wade among the dolphins to kill them. Usually, the entire school is killed.

Drosophila A genus of fruit flies often used as experimental subjects in laboratory studies of chromosome structure and evolution, including *D. melanogaster*, the familiar fly-in-a-bottle of high school and college genetics laboratories.

ductus arteriosus A connection between the pulmonary artery and aorta in mammalian fetal circulation.

dugong A strictly marine, herbivorous mammal foraging at the bottom, primarily on seagrasses, and propelling itself with a triangular caudal fluke.

duodenum The proximal part of the small intestine that is fixed to the dorsal abdominal wall and does not have mesenteries.

dura mater The outermost protective layer covering the brain and spinal cord in vertebrate animals.

E

eared seals Seals of the suborder Otariidae. They propel themselves with their fore flippers underwater and "waddle" with all four limbs on land. So termed because they have external pinnae, or ear flaps, visible to the casual observer.

earless seals Seals of the suborder Phocidae. These "true seals" all use blubber to thermoregulate, do not have external ear pinnae, use their hindlimbs to propel themselves in water, and have a hunching, caterpillar-like mode of locomotion on land.

echolocation The production of high-frequency sound waves and reception of echoes to locate objects and investigate the surrounding environment.

ecophenotypic Resulting from effects of the environment rather than the genome.

ecosystem A biological community and its environment, functioning as a unit in nature.

ecosystem model A mathematical representation of an ecological system that attempts to include all the major components of the system.

ecotype Ecological form or variation of a species.

ectoparasite A type of parasite that resides on the external surface of its host.

ectotympanic One of the bones that make up the skull in mammals. In primitive mammals, it is in the form of a horseshoe, and the tympanic membrane (eardrum) is suspended by it; this shape is retained by sirenians. In most mammals, the ectotympanic consists of additional flanges of bone that may form the wall of the middle ear (as in cetaceans and pinnipeds) and that may fuse with other skull bones.

effective population size The number of individuals in an ideal population with a level of genetic variation equal similar to that observed, i.e., the number of individuals participating in breeding.

electrolytes Charged ions such as sodium, chloride, potassium, calcium, and magnesium that are important components of the internal fluid of an organism.

embryonic diapause Delayed implantation of the blastocyst (embryo) in the uterine wall and a pause in the process of development. Implantation reactivates the blastocyst and allows placental gestation to proceed.

emmetropia The proper eye refraction, as opposed to myopia (near-sight) and hyperopia (far-sight).

empirical Describing phenomena that are directly observable or measurable or that require a minimum of models and assumptions to be characterized.

encephalization An evolutionary increase in brain size relative to body size.

encephalization index or **quotient** A numerical comparison of brain size to body size.

endangered Describing a species or population that is in danger of extinction in the near future.

endemic Restricted or peculiar to a specific locality or region; describing a species that occurs in only one geographic area (e.g., an island).

endocranium The internal space within a cranium that houses the brain and surrounding tissues.

endocrine Referring to a ductless gland that secretes hormones.

endotherm An animal that generates its own body heat for thermoregulation. Mammals and birds are endotherms.

endothermic Producing its own body heat for temperature regulation; in popular use, warm-blooded.

endothermy The physiological condition wherein the body temperature of an animal is controlled by the generating of heat produced in its own body.

energy reserve The amount of energy usually stored as fat in the body of the animal that is excess to current requirements.

entoconid The cusp (elevated part of a tooth) on the posterolingual side of the posterior heel of a lower cheek tooth.

environmental carrying capacity See CARRYING CAPACITY.

Eocene **1.** The geologic epoch spanning 55 to 34 million years ago during which most, if not all, of the lineages leading to modern carnivorans evolved. **2.** The sediments deposited in this time period.

epimeletic behavior Behavior that supports caregiving, nurturing, and survival in young. This also includes the soliciting of caregiving behavior by other animals.

epipelagic Occurring at or near the surface in pelagic waters.

epithelial cells Cells that form firmly coherent layers of tissue on exposed surfaces.

epizoic Referring to nonparasitic animals that attach themselves to the outer surface of another, normally larger, animal.

epizootic **1.** Referring to a temporarily prevalent and widespread disease in an animal population. **2.** A disease outbreak of this type.

escort A term for an adult male humpback whale that accompanies a female with calf on the breeding ground.

estrous Relating to the stage of the mammalian sexual cycle when females are receptive to copulation.

estrus The time in a female's reproductive cycle when she is "in heat," i.e., fertile and receptive to mating. A characteristic of mammals other than primates.

estrus lordosis See LORDOSIS.

etiology **1.** Generally, the assignment of a cause or reason for some condition or event. **2.** The field of science that studies the causes of diseases.

eumustelids Fossil and extant mustelids that belong to one of the five currently recognized subfamilies; the Mustelinae (weasels), Melinae (badgers), Mellivorinae (honey badger), Lutrinae (otters), and Mephitinae (skunks).

euphausiid *Any of an order (Euphausiacea) of small, usually luminescent shrimp-like crustaceans, forming an important part of the marine zooplankton; commonly known as krill.*

eustachian tube A slender tube that connects the tympanic cavity with the pharynx and serves to equalize air pressure on either side of the eardrum; the remnant of the embryonic first gill (or pharyngeal) pouch.

Eutheria An infraclass of therian mammals including all living forms except the monotremes and marsupials.

evoked potential An electric response of the brain to sensory stimulation; reflects an integrated simultaneous activity of many neurons evoked by the stimulus.

evolution Descent with modification, with ancestral species giving rise to one or more descendant species.

evolutionary stable strategy Patterns of reproduction or behavior that have equal fitness value.

exon An uninterrupted nucleotide sequence in a locus that is translated into amino acids.

exoskeleton Hard supporting structure made of chitin, secreted by a crustacean and external to the epidermis.

exponential growth Population growth for which a constant percentage is added each year, which means that a greater number of animals are added to the population each year.

ex situ conservation The process of maintaining and breeding animals or plants outside their natural environment.

extant Still existing, not extinct.

extinct No longer living; describing a taxon for which there is no reasonable doubt that the last individual has died. A taxon is considered extinct in the wild when the only surviving individuals exist in cultivation, captivity, or a naturalized population outside the past wild range.

extinction The irreversible disappearance of a population, species, or higher taxonomic group.

extirpation The extinction of an organism in part of its range; loss or removal of part of a population.

extradural Referring to a location superficial to the dura mater, usually within the vertebral canal.

F

facultative "As need dictates;" referring to those animals that can or do live in one particular environment, but are also reasonably well adapted to another environment. For example, facultative river dolphins live in both ocean and river systems. Cf. OBLIGATE.

falcate Recurved and usually pointed; sickle-shaped.

fast ice A term for stable ice that is attached to land.

fasting A limited period of not eating or abstaining from food. Differs from starvation in that it is usually a periodic event for which the animal prepares by laying down extra body fat.

fathometer A sonar that is directed downward to measure water depth.

fatty acid A component of fat molecules. Fats are composed of three fatty acids (of varying carbon chain length; from 2 to 24 or more) attached to a glycerol backbone.

fecundity **1.** The potential level of female reproductive performance in a population; i.e., the average maximum number of offspring that females may bear during their fertile years. **2.** The actual average number of live births (more specifically, of female offspring) per year per female.

feedback loops A process through which substances or conditions occurring in the blood stimulate (positive) or inhibit (negative) the release of hormones responsible for affecting changes that modify the physiological state.

female choice A mechanism of sexual selection in which females prefer to mate with males exhibiting particular qualities, such as bright colors or vigorous displays, and reject other males.

female sexual maturity The stage of female sexual development in which ovulation occurs. Most cetaceans conceive at first ovulation and past ovulations are identifiable on ovaries.

fertilization Union of the sperm and egg.

fibrosis A thickening and scarring of connective tissue, as may result from disease or injury.

filter feeding Method used by some marine mammals to strain small particles of food from the water, using baleen or serrated teeth.

fineness ratio Ratio of body length to maximum diameter.

fisheries The enterprise(s) of catching or harvesting fish for human consumption.

fish ladder A man-made structure that allows fish to pass upstream with no more effort than they would use to swim against natural river rapids.

fissipeds The group of four-legged, mainly carnivorous mammals with toes separate from each other; includes bears, otters, dogs, cats, raccoons, and hyenas.

fitness The ability of an organism to survive and to transmit genetic information to future generations.

flaw zone An area of labile, fractured or broken ice; caused by various factors that result in impingement or interaction among different types of sea ice, e.g., between drifting pack and shore-fast ice.

flensing The process of removing the blubber from a marine mammal carcass.

flipper The flattened forelimb of a marine mammal.

flippering The act of slamming the pectoral fin, or flipper, on the surface of the water.

flotsam The traditional term for bits of debris floating at the surface or in the water column, usually but not necessarily of human origin. Contrasted with **jetsam**, which is human debris that has been purposefully discarded.

flukes The horizontally spread tail of a whale (in contrast to the vertical tails of fish).

fluking The act of raising the tail, or flukes, above the surface of the water during the beginning of a dive.

food web The interconnection of species through their diets.

food web competition A mutually disadvantageous interaction that occurs due to indirect competition for a shared resource, such as when there is overlap of the trophic flows supporting marine mammals and fisheries.

foraging Searching for prey; the process of finding, catching, and eating food.

foramen ovale An opening between the right and left atria of the mammalian fetal heart.

foregut The anterior portion of the digestive tract, which includes the stomach.

forestomach Cetacean stomach chamber lined with stratified squamous epithelium; lies between the esophagus and the main or fundic stomach.

fossil The prehistoric remains of once-living organisms, either extinct or living species.

free hormone Any hormone in the blood not bound to proteins and therefore more readily available to influence cellular functions.

fundic The portion of the stomach distal to the cardiac portion, containing the fundic glands.

G

gadids Fish species of the cod family (Gadidae).

gape The mouth in cetaceans, usually referring to the junction of upper and lower lips.

gastric Relating to or situated in the stomach.

gene The coded information inside cells, which tells the body how to make enzymes, proteins, and other molecules necessary for life.

gene/allele frequency The proportion of gene copies in a population of a particular type; e.g., if 40% of the alleles in a population are type W (as opposed to w), the frequency of W in that population is 0.4.

gene flow The exchange of genetic material within and between populations.

genetic bottleneck A severe reduction in genetic diversity.

genetic diversity Variation in the chromosomes of a community of organisms, due to a large number of slightly dissimilar ancestors.

genetic drift Random changes in the gene frequencies of finite populations.

genetic fingerprinting A method of uniquely identifying an individual animal from a sample of tissue.

genotype The hereditary or genetic makeup of an individual.

geochronology The study of time in relationship to the history of the earth.

geologic range The geologic time span between the first and last appearance of fossil taxa.

gestation The period of time during which the embryo and later the fetus is carried by the mother in the pregnant state.

gilling The process of catching a fish by its gill covers, usually in a mesh of netting, so that the twine, under the gill covers, prevents the fish from moving backwards, while forward movement is prevented by the mesh of the net encircling the fish's head.

gill net A fishing net that is suspended in the water more or less vertically and ensnares fish by the gill covers as they try to swim through its meshes.

glucagon Protein hormone formed in the pancreas that when released to the blood increases the glucose content of the blood by increasing the breakdown of glycogen in the liver.

glucocorticoid Steroids such as cortisol and corticosterone produced by the adrenal cortex and affecting a broad range of metabolic and immunologic processes.

gluconeogenesis The synthesis of glucose from other carbon sources, occuring primarily in the liver.

glycogen The polysaccharide in which carbohydrate is most commonly stored in muscles and liver.

glycolysis The series of reactions that convert glucose to pyruvic acid.

grade A cluster of species that have a common pattern of organization but are not necessarily a clade.

granuloma The product of a type of inflammation, resulting in the formation of distinct nodules of inflammatory tissue.

gravid Pregnant with young (whether live young or eggs).

gross annual recruitment rate The product of the proportion of females in a population, the proportion of sexually mature females, and the annual pregnancy rate.

ground A term for an area of ocean where whalers find abundant sperm whales.

group selection The principle or phenomenon that differences in the attributes of groups are related to differences in group survival, particularly when the groups are competing with each other.

growth layer group (GLG) A repeating or semirepeating pattern of adjacent groups of incremental growth layers within the dentine, cement, bone, or other persistent tissue, which is defined as a countable unit. Such a unit must involve at least one change in appearance.

growth layers Incremental layers deposited in structures that persist and reflect growth or physiological processes at the time of deposition.

groyne A transverse structure that deflects water flow to prevent erosion of an embankment.

gubernaculum A fibrous cord connecting the testis to the scrotum that usually plays a significant role in testicular descent.

gyrification The degree of folding of the cerebral cortex.

H

habituation A gradual waning of behavioral (or physiological) responsiveness over time, as an animal learns that a repeated or ongoing stimulus is lacking in significant consequences. Cf. SENSITIZATION.

hair cell A special kind of cell that has tiny hairs projecting from its surface into the intercellular space. Movement of the hairs is registered by neurons that contact the hair cell. Hair cells are found in the ear of mammals.

halogenated organic compounds Organic compounds, usually anthropogenic or produced by the breakdown of anthropogenic compounds, that contain chlorine or fluorine atoms. Many, including organochlorines such as DDT and the PCBs, break down slowly when released into the environment and are potentially pathogenic.

hand-harpoon whaling A historic Japanese whaling technique that used hand harpoons and lances.

haplotype A unique DNA sequence or series of sequences.

harem A group of females whose breeding is controlled by a single male who seeks to prevent other males from breeding with them.

harpoon A fishing spear composed of a barbed head, a shaft, and a line that connects the shaft to a speared animal.

harvest The deliberate taking of wild animals, usually by hunting, netting, or trapping (not including live capture or removals for scientific purposes).

haulout The act of a seal leaving the ocean and crawling onto land or ice.

heat increment An increase in metabolism associated with the processing and digestion of food.

hemoglobin The iron-containing protein that binds to oxygen and is found in red blood cells.

hemopoietic tissue Tissue in which blood cells are formed (e.g., red blood cells are formed in the spleen of developing mammals and in the bone marrow of adults).

hepatic Relating to or occurring in the liver.

herbivore A feeder on plants.

herbivorous Plant-eating.

hertz A measure of frequency corresponding to one cycle per second.

heterodont Having teeth of different types.

heterodont dentition A type of dentition in which there are different tooth shapes in different parts of the mouth: incisors and canines in front and premolars and molars in back. Cf. HOMODONT DENTITION.

heterodonty See HETERODONT DENTITION.

heterospecific Describing an individual of a different species from another.

heteroxenous Describing a parasite life cycle involving more than one host.

heterozygosity The proportion of individuals in a population of diploid organisms that has two different alleles at a given locus.

heterozygous Having one or more pairs of dissimilar alleles (alternative forms of a gene).

hilus The point where the renal artery enters the kidney and the renal vein and ureter exit.

Hippopotamidae The mammalian family that includes extant hippopotamuses and their close extinct relatives.

histogram A graph showing statistical distribution of the probability of events, e.g., how frequently cells of one or another size appear in the overall cell population.

holotype A single specimen laying at the base of the scientific name of a species or subspecies.

home range The total area covered or traversed by an individual animal during the course of normal activities.

homodont Having teeth of the same type.

homodont dentition A type of dentition in which all of the teeth have similar size and shape. Cf. HETERODONT DENTITION.

homodonty See HOMODONT DENTITION.

homologous Pertaining to a relationship between corresponding parts in different organisms due to evolutionary development from the same structure, such as the wing of a bird and the flipper of a dolphin.

homoplastic Describing a character whose presence in various species is not due to a common origin.

homoplasy Similarity in character state in two or more groups that are not inherited from a common ancestor but evolved independently in each group.

homozygosity The proportion of individuals in a population of diploid organisms that has two identical alleles at a given locus.

homozygous Having one or more pairs of identical alleles (alternative forms of a gene).

hormone An organic compound produced by an endocrine gland that affects other tissues and organs within the body; e.g., the hormone progesterone is secreted by the corpus luteum and stimulates the uterus for implantation.

hormone-sensitive lipase An enzyme inside adipose cells that mobilizes free fatty acids stored in triglycerides and makes them available to other cells.

hydrofoil **1.** An asymmetrical blade whose shape produces lift forces due to differential fluid flow around its upper and lower surfaces. **2.** A wing-like limb flapped underwater to produce lift; e.g., penguin "wings."

hydrophone An underwater microphone.

hyoid apparatus A set of bones and/or cartilages attached to the base of the skull that help move the tongue and larynx during feeding and swallowing.

hyperglycemic Describing a condition in which blood glucose concentration is greater than normal.

hyperoxic Describing a gas mixture having a higher concentration of oxygen than in normal air.

hyperphagia Intense feeding.

hyperventilation Increased total ventilation produced by tidal volume and ventilation rate above the resting rate.

hypoconal crest The crest extending to the cheek side from the hypocone on an upper cheek tooth or to the tongue side from the hypoconid on a lower cheek tooth.

hypocone The cusp on the postero-lingual side of an upper cheek tooth of a derived placental mammal having quadritubercular (four-cusped) teeth.

hypoconid The cusp on the postero-labial side of the posterior heel of a lower cheek tooth.

hypoinsulemic Describing a condition in which the level of insulin in the blood is lower than normal.

hypometabolism A metabolic rate that is less than resting or basal metabolism.

hyponatremia An abnormally low blood concentration of sodium.

hypoxia Reduced availability of oxygen.

Hz Short for HERTZ.

I

ichthyophagous Feeding on fish.

igneous rock Rocks derived from the cooling and solidification of a magma or lava.

ileum The distal part of the small intestine.

immunodepressive Negatively affecting any aspect of the immune response system.

inbreeding Reproduction with a mate more closely related to the individual than the average pair in the population are related to each other.

inbreeding depression Diminution of growth, fertility, or survival as a consequence of inbreeding.

indirect fitness The gene contribution of an individual to the population through the relatives that it successfully aided in rearing and that would not have existed without its help.

infanticide The killing of young by parents or other members of the same species.

infrasonic Describing sound that is lower in frequency than the minimum audible to humans. Some baleen whales produce infrasonic calls.

infrasound Sound below the human hearing threshold, or 20 Hz (cycles per second). These sounds approximate a very low frequency roar or vibration.

insectivorous Feeding mainly on insects, and often also on other small invertebrates such as scorpions, spiders, worms, and snails. Insectivores are members of the Insectivora, a group of small mammals such as shrews and hedgehogs.

***in situ* conservation** The process of conserving animals or plants within their natural environment, in habitats within which evolutionary processes are maintained.

instar A juvenile stage of invertebrate development, which may be a configuration quite distinct from the adult.

insulin A protein hormone released by the pancreas that stimulates the uptake of glucose by peripheral tissues.

intermediate host A host in which a parasite develops to some extent but not to sexual maturity. Where more than one intermediate host is involved in a life cycle, they are ordered in chronological sequence as first, second, etc.

intermodal transfer The transfer of sensory information from one sensory modality to another, e.g., from vision to somatic sense and back, from vision to echolocation and back.

interspecific Involving individuals of different species.

intraspecific Pertaining to a level below or within a species (e.g., subspecies, population, deme).

intrinsic rate of increase The maximum rate of increase a species is capable of; thought to occur at a relatively small population size where a species has its greatest rates of reproduction and survival.

introgression The incorporation of genes of one species into the genetic constitution of another species, as by means of interspecific hybridization.

intron The part of the nucleotide sequence at a protein-coding locus that is transcribed into messenger RNA but not amino acids.

Inuit The native people of Arctic Chukotka, Alaska, Canada, and Greenland, popularly known as Eskimos.

Inupiaq *plural*, **Inupiat** An Inuit person.

invasive sampling The collecting of tissue samples in a manner that requires penetration of the epidermis.

involucrum The internal medial part of the tympanic bulla of cetaceans, which is made of extremely dense and heavy (pachyostotic) bone.

ischemia A blockage or reduction of blood flow that interrupts oxygen supply.

ischium The dorsal posterior part of the hip bone.

iteroparous Describing or referring to animals that reproduce more than once.

J

jejunum The middle portion of the small intestine (From a Latin word for dry; this part of the intestine was often empty in cadavers because of postmortem peristalsis.)

jetsam See FLOTSAM.

junk A complex arrangement of whitish tissue beneath the spermaceti organ, saturated with spermaceti oil.

K

karyotype A display of the chromosomes.

kelp Algae belonging to the division Phaeophyta, which includes the large "macroalgae" commonly known as seaweeds.

ketone bodies Any of three compounds—acetoacetate, acetone, and β-hydroxybutyrate—that can be produced by the liver as a result of lipid oxidization.

ketosis Accumulation of ketone bodies in the blood, usually associated with prolonged fasting or excessive lipid oxidation.

keystone species A species whose presence in (or absence from) a given ecosystem has a significant influence on the structure and function of the system, disproportionate to its numerical abundance.

killer whale The largest species (*Orcinus orca*) of the family Delphinidae, an aggressive cetacean that preys upon other marine mammals.

kinematics The study of motion. Often used in reference to the movement of limbs relative to the body of active animals.

kin selection The actions of an individual that lower the individual's own chances of survival and reproduction, but that benefit their relatives and thus indirectly contribute genes to the population.

kleptogyny Female stealing by males from the territories of other males, for the purpose of mating.

krill A general term describing shrimp-like crustaceans in the family Euphausiidae. Krill form an important food resource for filter-feeding marine mammals.

k-selection The reproductive strategy of a species that tends to grow slowly and have relatively few offspring, but that has a longer life span and parental involvement in the rearing of young. Certain large mammals are cited as an example of k-selection. Contrasted with an r-selected species, which has more rapid growth and a large number of offspring, but a shorter life span and negligible parental involvement.

L

lactation The production of milk by a female mammal for the feeding of young.

lactose A sugar found in some milks.

Lagrangian study The study of individual movement.

laminar flow A smooth and steady flow in which particles travel along a well-defined path.

lance A spear with a blade on both sides, thrust into a harpooned animal for killing.

land fast ice Polar ice that forms large sheets continuous with the shore. It is generally more persistent and stable than pack ice, which floats free of the land.

landing sites Traditional areas used by nonbreeding males for resting, playing, and other activities. In old sealer's jargon, landing sites were called "hauling-out grounds."

lanugo Soft, dense, downy hair that covers the fetus of some mammals; usually shed before or shortly after birth; this persists for up to several weeks after birth on some pinnipeds.

laparoscopy The examination of abdominal organs, including the reproductive tract, by means of an illuminated visual instrument (laparascope).

large-type whaling A historic form of Japanese coastal whaling that took sperm and baleen whales other than minke whales using a vessel and harpoon cannon of large size.

larynx The group of cartilages and muscles in the neck that house the vocal cords and are used for sound production in most mammals. In odontocetes, the larynx is not the main sound-producing organ, and it projects far rostrally, reaching the posterior side of the palate.

lateral Away from, or relatively farther from, the middle of the body.

lead A long linear area of open water or thin, newly formed ice; this occurs along shorelines, at the seaward margin of shore-fast ice, or in the drifting pack; often persistent or recurring.

lead line A weighted line onto which netting material has been fixed in order to keep part of the netting relatively low in the water column, typically on or near the seabed.

lek A traditional display site where males gather to defend small individual territories (that lack essential resources) and advertise for mates. (From a Swahili word for a mating ground.)

lekking The social system in which males gather on a communal display ground, and females choose mates by some criteria of "maleness."

length-specific speed Speed measured using the body length of the animal as a scale and calculated as the velocity of the animal divided by the body length.

Leydig cells Testosterone-producing cells between the seminiferous tubules of the testis.

life history The significant features of the life cycle of an organism, particularly the strategies influencing reproduction and survival.

lighting regime The ratio of number of hours of light versus number of hours of dark in a 24-hr period (light:dark).

limiting resource A resource whose relative abundance is a determining factor in the size of a given population.

lineage Ancestor-descendant populations of organisms through time.

lipoprotein lipase A tissue-bound enzyme that hydrolyzes circulating triglycerides in the blood, enabling transport of free fatty acids into cells.

lithification The conversion of a newly deposited sediment into solid rock, involving processes of compaction, cementation, and crystallization.

lithology A description of a rock unit based on characteristics such as color, mineralogy, and grain size.

lithostratigraphy The study of rock strata with emphasis on the lithology, succession, and correlation of strata.

lobster krill Larval crustaceans forming dense, often red, shoals in temperate waters.

lobtailing A behavior in which a whale slams its flukes down on the water, usually repeatedly.

locus The position on a chromosome/mtDNA molecule at which the gene for a particular trait or an intron resides.

longevity The life span of an individual; how long an organism lives. Maximum longevity (the longest any single member of a species or population has lived) is distinguished from average longevity (the average life span of all individuals in a year class or group of year classes). Average longevity cannot be determined until all of the animals in a year class have died.

long line A buoyed line onto which are attached numerous branch lines each terminating in a baited hook. Long lines may extend for tens of kilometers and are usually left to drift in the surface waters of the ocean to catch large pelagic fish.

lordosis A reproductive behavior of females in which they arch their back in a manner that raises their rear end upward to make mounting by the male easier.

lower risk A description of a taxon that has been evaluated for potential population decline, but that does not satisfy appropriate criteria to be classified as vulnerable, endangered, or critically endangered.

low-frequency active sonar (LFA) A naval sonar system designed to detect and locate quiet submarines at long range. Operates at frequencies below 1 kHz (typically 100–500 Hz) and at nominal source levels up to at least 230 dB re 1 mPa.

luciferase An enzyme involved in the chemical reaction to create bioluminescence.

luciferin A substrate involved in the chemical reaction to create bioluminescence.

lumbar Describing or located in the region near to the portion of the vertebral column between the thorax and the sacrum.

lunge A term for a thrusting of the forward part of an animal through the water surface, showing less than about 40% of the body (often the result of feeding at the surface).

lutrine A member of the otter subfamily (the Lutrinae).

M

magnetic declination The angle between the Earth's surface and magnetic lines of force for the Earth.

magnetite A magnetic mineral that is composed of iron oxide.

main stomach The glandular portion of the cetacean stomach, lying between the esophagus or forestomach and the connecting chambers.

maintenance metabolism The energetic cost associated with the maintenance of all physiological processes necessary to sustain an animal.

maktak Northern Alaskan Inuit term for the skin and blubber of whales.

male sexual maturity The stage of male sexual development in which all seminiferous tubules at the testicular center produce spermatozoa. Sperm production starts before this and testicular growth continues after.

management unit A group of animals that is the target of a particular management measure.

manaq or **manaqtuun** Northern Alaskan Inuit term for a retrieval hook used during ice edge seal hunting.

manatee A wholly aquatic herbivorous mammal generalist, foraging throughout the water column in fresh or salt water, and propelling itself with a broad caudal paddle.

maritory Underwater territories held by males.

mark-recapture A set of methods for estimating one or more of abundance, survival, and recruitment by recording repeated sightings or captures of animals, some of which are identifiable from marks previously placed on them. Increasingly, natural marks are used, identified from photographs or DNA fingerprinting.

marsupial Members of the Marsupialia, mammals found mainly in Australasia and South America, which give birth to very small young that then develop while attached to the mother's teats, often in a pouch, e.g., the kangaroo, opossum, wombat.

mass die-off Mortality on a large scale that may result in many strandings.

mass stranding The simultaneous stranding of two or more animals other than a female and her offspring.

mastoid process A component of the periotic bone (which makes the inner ear) that can be seen on the lateral face of the cranium.

mate choice competition A mechanism of sexual selection in which males compete among themselves by attempting to entice and attract females with visual, acoustic, or pheromonal displays; females typically mate with the male having the most exaggerated display.

maternal care Any form of maternal behavior that appears likely to increase the fitness of her offspring.

mathematical model A representation of a system or a synthesis of observations and ideas that is translated into the language of mathematics to facilitate understanding and analysis of the system or process.

matriline A descent system in which daughters reproduce in their mothers' social unit, leading to a group of maternally related females.

matrilineal Describing a social unit in which group members are descendants of a single female.

matrilineal habitat fidelity The continued return to habitats first learned from the mother during the months before weaning, which may persist for generations.

maxilla or **maxillary bone** One of the two major bones found in the upper jaw of mammals, the other being the premaxilla.

maxillary crest The anterior portion of the maxilla, which is enlarged in cetaceans due to telescoping of the cranial bones.

maximum net productivity level The population size that will result in the maximum growth rate (in number of individuals added to the population per year).

maximum sustainable yield The maximum human harvest from a population that can be sustained continuously and, for a non-selective harvest, that is equivalent to the maximum net productivity level.

medial Toward, or relatively closer to, the middle of the body.

mediastinum In mammals, the region between the lungs.

melanin The pigment responsible for dark coloration in the skin and eyes of many animals.

melon A lump of fatty tissue that forms the "forehead" of toothed whales and that is thought to funtion as a means of focusing sound for echolocation.

Mendelian inheritance Loci that are inherited from both parents.

menopause The termination of reproductive function in a female, as a result of aging.

mesentery The double layer of peritoneum that suspends the abdominal organs from the dorsal wall; it contains blood vessels and nerves that supply the organs.

mesonephros Embryonic kidney that functions only until the metanephros is formed and then regresses. Its duct (Wolffian) is retained in the male as the epididymis and ductus deferens.

mesopelagic Referring to the middle portion of the water column, generally from 200 to 1000 m.

mesosalpinx A special paired mesentery structure, forming part of the broad ligament, and supporting the oviducts.

Mesozoic An era of geological time, from about 285 million to 65 million years before the present, comprising the Triassic, Jurassic, and Cretaceous periods.

metabolic overhead The amount of energy expended by a lactating female for her own maintenance, relative to the total energy expended during lactation.

metabolic water Water that is produced as a result of the oxidation of food or stored body tissue.

metanephros Precursor of the kidney that will function postnatally.

metapopulation An overall population consisting of two or more subpopulations more or less isolated from each other, treated as a single evolutionary or management entity.

metatarsal A bone in the middle portion of the hind foot.

microallopatric Sharing a geographic range but occurring in different habitats or portions of a habitat, so that there is no mixing on a small spatial scale.

microsatellites Non-coding short tandem repeats in the nuclear genome; those having a variable number of repeats (alleles) are used in population analysis.

migration The process of seasonal movement of individuals between different geographic locations.

migration count A sample count of migrating whales carried out from a coastal watch point from which population size is estimated.

mimicry Behavior resembling the behavior of others occurring in the same locale or within some relationship of time and space; an important component of early social development. Various forms of mimicry are exhibited by many animals for separate survival strategies.

mineralocorticoids Steroids such as aldosterone produced primarily in the zona glomerulosa of the adrenal cortex and regulating the metabolism of ions such as sodium and potassium.

Minoan Referring to the Bronze Age civilization centered on the Mediterranean island of Crete (c. 3000–1000 B.C.) prior to the Greek empire. (*Mino* was Crete's legendary king.)

mitochondria Small cytoplasmic organelles found in almost all living cells.

mitochondrial DNA A circular DNA molecule that is found within mitochondria in large numbers of copies. In mammals, mitochondrial DNA is inherited maternally, the gene sequence and contents are very conserved, and the DNA is composed of about 14,000–17,000 nucleotide base pairs.

molar One of the rearmost teeth used mainly for crushing and chewing.

molt or molting The relatively abrupt shedding of an old outer covering (in mammals, the skin) to be replaced by a new layer recently formed underneath.

monestrous Having a single estrous cycle once each year.

monogamy A mating system in which one male and one female are together for at least one seasonal breeding cycle.

monomorphism The existence of similar morphology in males and females, usually in both body shape and color.

monophyletic Pertaining to a group that shares a common ancestor and includes all descendants of that ancestor.

monophyly The status of a group that includes an ancestral species and all of its descendants.

monophyodont Developing only a single set of teeth, rather than deciduous and adult sets.

monotypic Being the sole type in its group (genus).

monoxenous Describing a parasite life cycle in which only a single host is used.

monsoon A constant, seasonal wind within the tropics.

morphological Having to do with the appearance or form of an individual or species.

morphology **1.** The physical appearance or form of an individual or species. **2.** The study of such properties.

motorboating A behavior pattern of very rapid tail slapping (two to three slaps a second) in trains up to 15 sec in length.

motor pattern A pattern of coordinated movements, positions, and postures of the body that is recognizable, repeated, and characteristic of particular classes of movements or functions.

mtDNA See MITOCHONDRIAL DNA.

multiparous Describing a female that has had more than one pregnancy, as contrasted with nulliparous (no pregnancy) and primiparous (first pregnancy).

multireniculate Describing a type of kidney that contains many reniculi.

multispecies model A mathematical representation that includes a minimum of two interacting species in the system.

multivariate analysis Statistical methods that can be used to simultaneously examine multiple variables and their interactions.

muscular hydrostat A three-dimensional array of muscles having constant volume, capable of highly controlled, precise, and varied movements, and not dependent on bony attachments for the support of antagonistic actions of the muscles. Examples include the tentacles of squid, trunks of elephants, and tongues and lips of mammals.

museau de singe In sperm whales, a valve-like clapper system at the end of the right nasal passage, thought to be the producer of the whale's clicks.

mustelids or **mustelidae** Members of the family Mustelidae of carnivorous mammals, which includes the otters, stoats, minks, and fishers.

musteloids All members of the family Mustelidae and its generally accepted sister taxon Procyonidae, as well as those stem taxa that are thought to have given rise to this clade.

mutation An alteration in a gene that causes it to produce a faulty product, or no product at all.

mutualism A relationship of organisms in which individuals engage in actions that are mutually beneficial.

myoglobin A protein in mammalian muscle that carries oxygen. Hemoglobin has a similar function in the blood.

mysid A shrimp-like crustacean of the order Myscidacea.

Mysticeti (mysticetes) The toothless or baleen (whalebone) whales, including the rorquals, gray whale, and right whales; the suborder of whales that includes those that bulk feed and cannot echolocate. Their skulls have an antorbital process of the maxilla, a loose mandibular symphysis, a relatively small pterygoid sinus, and the maxillary bone telescoped beneath the supraorbital process of the frontal.

N

nanuq Northern Alaskan Inuit term for a polar bear.

nares Openings of the nasal cavity.

nasal turbinate Specialized structures in the nasal passage of mammals that allow for the recovery of water.

nasolaryngeal air sacs Air sacs of the larynx that are continuous with the nasal passages.

natal site The group of islands or rookery where animals were born.

natchiq Northern Alaskan Inuit term for a ringed seal.

natriuresis Excretion of sodium ions in the urine.

natural mark(ing) Any distinctive feature of an animal that is useful to researchers for individual identification, without any involvement by the researcher in producing the mark.

natural selection One of several evolutionary mechanisms; it accounts for an attribute becoming more common (selected) because of some benefit that leads to more offspring being produced.

nauplius larvae Developmental series of free-swimming, nonfeeding planktonic euphausiid larval stages. It is the earliest and most basic type of euphausiid larva.

necrosis The death of cells or tissue, caused by disease or injury.

nematodes Cylindrical worm-shaped invertebrates generally known as roundworms; widespread in diverse habitats. Many are parasitic on vertebrates, including marine mammals.

neocortical Referring to the dorsal region of the cerebral cortex, which is the most recently evolved part of the mammalian brain.

neomorph A new structure produced by evolution, in a species or lineage in which no comparable structure existed previously.

neonatal Referring to or occurring in the period immediately after birth.

neonate A newborn individual.

neoplasia The process of formation of a new and abnormal growth of tissue.

nephron The functional unit of the kidney. The nephron is a tubule with regions specialized for the reabsorption and secretion of various solutes, processes which ultimately produce urine from fluid filtered from the blood. Each kidney (or reniculus) can contain millions of nephrons.

neritic Referring to or occurring in waters above the continental shelf.

net sounder An acoustic transmitting device used to try to ensure that fish schools enter a trawl. The device is usually fixed to the trawl head line and provides the ship captain with an indication of the position of the device in relation to the surface and the seabed, and also the position of fish schools underneath the device.

net whaling A historic whaling method in which whales were first driven into nets and then harpooned.

neurohypophysis Downgrowth of the base of the hypothalamus in the brain, containing the secretory extremities of neurons extending from the brain and producing the hormones oxytocin and vasopressin.

neutering Surgical removal of the testicles; often used for permanent contraception.

neutral buoyancy A state in which the upward force of buoyancy is equal to the downward force of gravity.

niche The ecological space or role occupied by a particular species, making it distinct from other species in the same ecological system.

nitrogen narcosis A marked decrease in motor coordination and mental capacities, caused by increased concentrations of nitrogen gas in the brain and other nervous tissue.

nocturnal Active at night, while sleeping or at rest during daylight hours.

nominal species A term for any properly named and described (authored) species, whether or not it is recognized today as a valid species.

nonbasilosaurid archaeocete An archaeocete in the families Pakicetidae, Ambulocetidae, Remingtonocetidae, or Protocetidae. Members of this group were formerly included in Protocetidae.

nonessential amino acids Amino acids that can be synthesized.

nonesterified fatty acids A fatty acid that is not attached to a glycerol molecule.

noninvasive sampling The collection of tissue samples in a manner that does not require penetration of the epidermis.

nonsynonymous mutations Single nucleotide substitutions that result in amino acid replacements.

nontarget species A species that is taken in by a fishery even though it is not one that the fishery is primarily concerned with catching.

Norwegian-type whaling A technique of modern whaling, using a harpoon shot from a cannon mounted on a motor-driven vessel.

nulliparous Describing a female that has had no pregnancy, as contrasted with multiparous (more than one pregnancy) and primiparous (first pregnancy).

O

obligate Those animals consigned to a particular ecological regime by their evolutionary history. Obligate river dolphins can only live in fresh water. Cf. FACULTATIVE.

observational learning A process in which animals can acquire changes in their own behavior by observing as another or others engage in some behavior and experience positive or negative consequences.

oceanic Relating to or occurring in deep water off the continental shelves.

oceanic front The point at which two masses of seawater meet that differ in temperature, salinity, or both.

Odontoceti (odontocetes) The toothed whales, including sperm and killer whales, belugas, narwhals, dolphins, and porpoises; the suborder of whales including those able to echolocate. Their skulls have premaxillary foramina, a relatively large pterygoid sinus that extends anteriorly around the nostril passage, and the maxillary bone telescoped over the supraorbital process of the frontal.

offshore killer whales A provisional name for a genetically distinct population of killer whales recently identified from British Columbia, California, and southeastern Alaska, which appears to range mostly over continental shelf waters rather than nearshore waters. They are not observed to associate with either resident or transient killer whales, and their feeding habits are unknown.

ommatidium A single functional unit of a compound eye in an arthropod.

oocyte A developing egg cell in one of two stages. The primary oocyte begins differentiation near the time of birth; maturation is arrested until after puberty, when recruitment of the egg causes further differentiation toward potential ovulation.

operant conditioning The process of teaching a specific behavior by rewarding or reinforcing the occurrences of that behavior.

optimum sustainable population A term used to describe a population the size of which lies between the carrying capacity of the local environment and the population's maximum net productivity level.

organochlorines Synthetic compounds containing chlorine atoms such as PCBs and pesticides.

organogenesis The formation of organs and organ systems.

osmolality A measure of the osmotic pressure of a solution.

osmolarity Changes in the properties of a solution that result from the number of particles that are dissolved in it. The greater the number of dissolved particles, the greater the osmolarity of the solution.

osmoregulation The process by which an organism maintains its internal salt and water composition constant.

osmotic Referring to properties of solutions that depend on concentrations of dissolved salts and other substances.

osteological Relating to the bony structures.

osteology The study of bones and their structures.

osteosclerosis Increased density of bone due to replacement of spongy or cancellous bone tissue by compact bone tissue. In several groups of marine mammals, this condition is normal and characteristic rather than pathological as it would be in humans.

Otariidae (otariids) The eared seals (sea lions and fur seals), which use their foreflippers for propulsion.

otolith One of three calcareous bodies in the ear of a bony (i.e., teleost) fish, used in orientation.

overexploitation The reduction, as a result of overfishing, of the size of a population to below the level that provides the maximum sustainable yield. Sometimes referred to as "biological overexploitation," because there can be circumstances where it is economically optimal to reduce populations below their maximum sustainable yield levels.

oxidation The process of using oxygen to liberate energy from ingested food or stored tissue, resulting in the production of water and carbon dioxide.

oxygen store The total amount of oxygen available for aerobic metabolism. This oxygen can be a gas in the lungs, bound to hemoglobin in the blood, or bound to myoglobin in muscles.

P

pachyosteosclerosis A combined condition of osteosclerosis and pachyostosis, typically found in the thoracic skeleton of sirenians.

pachyostosis An increased volume of bone, resulting in a swollen appearance of individual skeletal elements.

pack ice Pieces of unstable seawater ice, often called pans, which vary from a few meters to several hundred meters in diameter. These pieces are not attached to land; instead they drift according to local current and wind conditions.

paedomorphosis The retention of juvenile characters in the adult form.

pagophilic Associated with ice.

PAHs polycyclic aromatic hydrocarbons; large groups of naturally occurring aromatic compounds containing two or more benzene rings fused together. Also, oil compounds derived directly (petrogenic) or indirectly via combustion (pyrogenic). Some of these compounds, such as benzopyrene, are known carcinogens.

palatine Either of the two bones that make up the palate.

pan bone A thin area in the posterior section of the mandible of a dolphin.

panmictic Describing the mingling of genetic material throughout a breeding population.

panmixia The free interchange of genes within an interbreeding population.

pantropical Occurring or distributed throughout the tropical regions of the world.

parapatric Referring to populations, species, or taxa whose ranges border each other but do not overlap.

parapatry The fact of occurring in adjacent or slightly overlapping geographical areas.

paraphyletic Describing a taxonomic group that does not contain all of the descendants of the most recent common ancestor of its members.

paraphyly A state in which not all the descendants of an immediate ancestor are included in a taxon; e.g., the taxon Reptilia is paraphyletic because it does not include birds, which are now described as arising from dinosaurs.

paratenic host See TRANSPORT HOST.

paraxonic Describing the hand or foot of a four-footed animal in which the axis of symmetry passes between digits three and four.

parental investment Behavioral and energetic effort expended by a parent on offspring that benefits the offspring at a fitness cost to the parent. Such fitness costs are often measured as a reduction in fertility or as an increase in mortality due to the effort expended on offspring.

parity Number of pregnancies and/or number of times a female has given birth; from the Latin parere "to bear." Nulliparous females have never been pregnant. A primiparous female is pregnant with her first offspring or has had only one offspring. Multiparous females have had more than one pregnancy or offspring.

partial pressure The portion of the total pressure of a gas mixture attributable to one gas component.

parturition The act or fact of giving birth.

pathogen Any organism or chemical that can cause disease as a result of infection or ingestion.

pathogenic Causing disease; harmful to an organism.

PCBs polychlorinated biphenyls; a family of toxic compounds formerly used in industry and manufacturing and frequently discharged into rivers in chemical wastes.

peduncle In cetaceans, the posterior portion of the body bearing the tail, or flukes.

pelage The hair coat of mammals.

pelagic Living or occurring in the open sea; e.g., pelagic dolphins mainly inhabit the deep water of the open ocean.

pelagic trawls Bag-like nets that are towed through the upper parts of the water column rather than near the seabed.

pelagic whaling A whaling operation that does not depend on the use of a land station for processing whales, but uses a floating factory ship (mother ship) or catcher boat with factory facilities.

pelvis A bone complex normally formed from the fusion of three bones (ilium, ischium, and pelvic) that forms the pelvic girdle and attaches to the sacral vertebrae.

perilymphatic duct A duct that carries the lymphatic fluids between the inner ear and the otic space of the cranium.

perinatal Relating to or occurring in the period immediately after giving birth.

permanent ice The core area of ice around both poles that does not melt completely in summer.

periotic The bone housing the inner ear of cetaceans. This complex bone is very dense and is loosely attached to the skull in odontocetes. It is frequently found as an isolated fossil and may be diagnostic as to the level of genus or species.

Perissodactyla (perissodactyls) An order of living and extinct mammals with hooves distinctive for being "odd-toed," a condition in which the weight of the limb is transmitted along digit 3. Examples include horses, tapirs, and rhinos.

peritoneal Relating to the peritoneum, the lining of the abdominal cavity.

pes The foot, consisting of tarsal (ankle) bones, metatarsals, phalanges, and adjacent tissues.

petasma A complex membranous plate on the inner side of a single pair of limbs in the male of several crustaceans. The petasma enlarges during sexual maturation and is used during copulation to aid in the transfer of spermatophores.

P450 enzyme system A group of enzymes induced by and metabolizing a wide range of natural products (e.g., hormones) as well as unnatural chemicals (e.g., dioxins, some PCBs, dibenzofuranes).

phalanges The bones of the toes.

pharynx The anatomical area posterior to the nasal cavity and mouth, where the passage for air crosses that for food. Air passes from the nasal cavity to the nasopharyngeal duct to the pharynx to the larynx to the trachea. Food passes from the oral cavity to the pharynx to the esophagus.

phenotype **1.** The visible or observable traits of an organism. **2.** More generally, all the collective morphological, physiological, or behavioral aspects of the individual; an expression of the genotype as influenced by environmental factors.

phenotypic Relating to the visible body form that is exhibited by an organism.

pheromone A body secretion that affects or influences the behavior of other individuals, such as a sex attractant.

philopatric Describing individuals that tend to return to breed near the site of their birth.

philopatry The fact of mating as an adult at the site of one's own birth. The importance of philopatry to social behavior and evolution are: (a) adults interacting with one another at a breeding site may be familiar to one another over successive breeding seasons and may even be related; (b) species may show strong genetic differentiation across their geographic ranges. Cf. SITE FIDELITY.

Phocidae (phocids) A family group within the pinnipeds that includes all of the "true" seals (i.e., the "earless" species). Generally used to refer to all recent pinnipeds that are more closely related to *Phoca* than to otariids or the walrus.

Phocoenidae The family of true porpoises.

phoresy The transportation of one species by another so as to benefit the transported species.

photic zone The depth in the ocean into which natural light penetrates.

photoidentification The use of photographs to identify animals individually.

photoperiodism The fact of an animal's being affected by phase changes in a day-night or light-dark cycle.

photophore A light-emitting organ composed of a cluster of light-producing cells, a reflector, and a lens. The luminescence produced by photophores in euphausiids is presumed to be an adaptation for swarming and reproduction.

photopic vision Vision in conditions of high luminance.

phycotoxins Pathogens produced by algae.

phylogenetic Relating to the evolutionary ancestry or lineage of an organism or group of organisms.

phylogenetic analysis A method of codifying and comparing heritable biological data for a group of organisms, including molecules, soft tissues, bones, and behavioral data, to formulate a hypothesis of how the organisms are related to each other (a **phylogenetic tree**).

phylogeny The evolutionary relationships among different taxa, usually at the species level.

phylopatry See PHILOPATRY.

phytoplankton Collectively, planktonic plant life.

pigment A dark compound that imparts color to hair, eyes, and skin.

pinna A flap of skin supported by cartilage, and sometimes moved by small muscles, that projects from the side of the head in vertebrates and functions as a sound funnel. In popular use, it is called the ear, but scientists reserve the term "ear" for the much larger organ of hearing, which includes many parts not visible externally.

pinniped One of a group of aquatic, mostly marine, carnivorous mammals; includes seals, sea lions, and walruses; all their limbs are fin-like, and they spend at least some time on land or ice.

piscivorous Feeding primarily on fish.

pisiform A small bone at the junction of the ulna and the carpus (wrist).

placenta The organ of metabolic interchange between fetus and mother.

placental Describing the members of a major group of mammals whose young develop in the womb supplied with nutriment and oxygen from the mother through a placenta; in contrast to the marsupials, in which significant development takes place outside the womb after birth.

plankton Collectively, the passively floating or weakly swimming plant and animal life of a body of water; usually minute.

plantigrade **1.** Walking on the sole with the heel touching the ground. **2.** An animal that moves in this manner.

plantigrady A foot posture in which the entire palm and sole of the forefoot and hindfoot are in contact with the ground in the standing position.

play An imprecisely defined category of behavior, especially in juvenile animals; generally including activities that, while having no immediate identifiable value, may benefit the animal in some other situation or at some later stage in life.

Pleistocene The first of two epochs in the Quaternary, extending from 2 million years ago until approximately 10,000 years ago.

pleomorphic Having more than one distinct form within a single species, group, or life cycle.

pleopod An anterior abdominal appendage modified for swimming.

plesiomorphic Describing shared primitive characters inherited from a distant ancestor.

plesiomorphy The existence of shared primitive characters (**plesiomorphies**) inherited from a distant ancestor.

plicae circulares (circular folds) Folds in the epithelium of the small intestine that serve to increase the surface area.

plicae semilunares (semilunar folds) Folds of the epithelium of the large intestine produced by the longitudinal muscles.

pneumotachograph A mechanical device to measure the volume and rate of flow of air moved in and out of a mammal's lungs.

pod In resident killer whales, a group of closely related matrilines that regularly associate with each other in preference to other matrilines within the community.

polar front The border between the cold waters of the Southern Ocean and the temperate water masses of the south Atlantic, south Pacific, and Indian Oceans (formerly known as the Antarctic convergence).

polychlorinated biphenyls See PCBS.

polycyclic aromatic hydrocarbons See PAHS.

polydont Having more teeth than the generalized mammalian number.

polydonty For mammals, an increase in the number of teeth above the primitive mammalian formula of 44.

polyestrous Having more than one estrous cycle in a single year.

polygynous Describing a mating system in which one male mates with multiple females during a breeding season.

polygyny A mating system in which one male mates with several females within one breeding season. The term usually refers to a mating system in which relatively few successful males breed with most of the females, while others do not mate. The reverse, one female mating with several males, is rare among mammals.

polynya An irregular-shaped area of open water or thin, recently formed ice completely surrounded by (usually heavier) ice; often persistent or recurring; this varies greatly in size, shape, and causal factors.

polyphyletic Describing or belonging to an artificial taxonomic group containing two or more species not sharing an immediate common ancestor.

polyphyly The status of a group that does not include the most recent common ancestor of all its members.

polyunsaturated fatty acid A fatty acid that contains two to six double bonds.

population A group of organisms of the same species occupying a particular area at the same time.

population bottleneck A rapid reduction in the size of a population, resulting in a loss of genetic diversity.

population stock See STOCK.

porpoise Any of several small cetaceans in the family Phocoenidae. The dorsal fin may be absent; teeth are spatulate or vestigial.

porpoising The behavior of penguins, dolphins, or whales leaping at least partially clear of the water surface during rapid swimming.

postcrania A collective term for bones that are not part of the skull, e.g., the vertebrae, limbs, hands, or feet.

postpartum After birth; especially, shortly after birth.

postreproductive Describing a female of certain toothed whales that ceases ovulating at an advanced age but well before her expected longevity.

practical salinity unit The measure of salinity of seawater, approximately equal to parts per thousand.

precautionary principle An ecological management philosophy that seeks to maintain natural resources by managing more conservatively when there is greater ignorance about the status of the resource.

precocial Being born in an advanced state of maturation and requiring relatively little adult care. In contrast, altricial young are born in a helpless state and depend heavily on adult care.

predation A situation in which an animal exerts time and energy to locate living prey and expends additional effort to kill and consume it.

predator An animal that obtains its food primarily or exclusively by hunting and killing other animals.

predatory Describing an animal that obtains its food by preying on other animals.

preening In birds, the act of smoothing or cleaning feathers with the beak of the bill.

preformed water Water that exists as water when it is consumed in the food or drunk.

premaxilla One of the two major bones found in the upper jaw of mammals. The other is the maxilla.

premaxillary sacs Premaxillary elements of the air sac system, which is a net of diverticula of the narial passages between the external nares (blowhole) and the bony nares of the skull.

premolar A tooth behind the large canine, used to slice or chew.

prepartum Describing or occurring in the time before birth, especially shortly before birth.

prey Animal that is hunted and killed by another.

primary production (productivity) Organic matter and/or energy produced or captured by organisms (plants) from inorganic compounds and incident solar radiation.

primiparous Describing a female that gives birth for the first time, as contrasted with multiparous (more than one pregnancy) and nulliparous (no pregnancy).

primordium See ANLAGE.

probability of identity The probability that two different individuals have identical genotypes.

procumbent Describing a tooth (generally apical) that tends to acquire a subhorizontal to horizontal orientation.

protocetid A member of the family Protocetidae, a paraphyletic family that is thought to have given rise to the basilosaurids.

proximate explanation An explanation that describes the immediate or short-term causes of a biological incident or occurrence, in contrast to ultimate explanations, which are historical (specifically, evolutionary) in nature. For example, a threat between neighboring territorial male sea otters can be said to have occurred because the two males encountered one another near their common boundary or had high levels of testosterone (proximate explanation).Or, it can be stated that the threats evolved as a low-risk alternative to fighting (ultimate explanation).

pseudocervix Folds of tissue, usually vaginal in origin, that are distal to the true cervix, but play a similar role or barrier as the true cervix.

psychophysical test A test in which an animal is trained to show the experimenter when it detects a physical stimulus, such as light, sound, or a chemical.

psychosphere Global, nutrient-rich, relatively biologically unexploited deep water.

pteropod Small molluscans with two "wings," with which they swim through the water.

pterygoid An anatomical process descending from the sphenoid bone.

pterygoid sinus An airspace adjacent to the flat pterygoid bones of the skull.

purse seine A type of fishing gear that surrounds fish schools with a vertical curtain of netting that is then pursed, or closed off, at the bottom by means of ropes and heavy winches, in order to prevent fish from swimming out of the bottom of the net.

pyloric stomach The most distal portion of the cetacean stomach, adjacent to the pyloric sphincter; contains pyloric glands.

Q

qargi Northern Alaskan Inuit term for whalers' ceremonial house.

R

race An interbreeding subgroup of a species that is genetically distinct and usually geographically isolated from other such groups of the same species.

radius A bone extending from the elbow to the wrist on the outside of the forelimb, opposite the ulna.

range The maximum extent of geographic area used by a species.

rank A designated level in a classification scheme.

raptoria Describing a process of feeding by seizing individual food organisms.

rare Not common, widespread, or generalized; not generally found.

reciprocity A behavior pattern in which individuals engage in helpful actions that will be repaid by the recipient.

refractive index A parameter of a light-transparent medium determining the degree of light refraction at a boundary between media with different indices. The more index difference, the stronger the refraction. The refractive index of a vacuum is 1, that of air is almost the same, and that of water and some eye media (anterior chamber liquid, vitreous body) is 1.33.

regression The mathematical relationship between two variables, e.g., body mass and brain mass.

reinforcement An event (reward or punishment) that follows a response and that increases or decreases the likelihood that the response will recur.

reintroduction The reestablishment of a species within its natural range.

release The act or technique of moving an animal that has been born in captivity, or that has been in captivity for long enough that it requires retraining in the skills required to survive, back into the wild so that the animal can become free-ranging and no longer under human supervision.

relict species Persistent remnants of formerly widespread biotas, typically existing in specific isolated areas or habitats.

remora A type of fish that has a modified dorsal fin to suck onto other fish, marine mammals, or turtles; also called "suckerfish."

renal Relating to or occurring in the kidney.

renal pelvis A funnel-like structure into which urine drains from the nephrons.

reniculus In discrete multireniculate kidneys, the anatomically independent functional units into which the kidney is divided. The reniculus resembles a miniature kidney with a cortex, medulla, vascular supply (renicular artery and vein), and ureteral tubule.

replacement yield The number of animals, which if removed from a population stock, results in the same number of animals at the end of the year as in the beginning.

reproductive ecotype An array of species of plants or animals adapted to the conditions of some breeding site and having inheritable features.

reproductive success **1.** The ability of an organism to reproduce. **2.** Specifically, the number of offspring successfully reared to independence by an individual adopting a particular strategy.

reproductive value The number of offspring that an individual of a given age can be expected to produce over the rest of its life discounted by the population growth rate.

resident killer whales A genetically distinct population of killer whales found in coastal waters of the northeastern Pacific Ocean, which feeds preferentially on fish and squid. Cf. OFFSHORE KILLER WHALES, TRANSIENT KILLER WHALES.

resilience The recuperative power of a population to recover from or absorb sudden environmental stress and deprivation.

resource Any item, factor, or condition that contributes to the ability of an organism to survive and reproduce; e.g., food, space, and mates.

respiratory acidosis A decrease in blood pH level, caused by an increase in the partial pressure of carbon dioxide that shifts the normal equilibrium of the bicarbonate-carbonic acid buffer system.

rete mirabile *plural*, **retia mirabilia** A dense, complex network of numerous small blood vessels.

reticulation The fact of crossing over or connection between lines of descent.

retroperitoneal Outside of but projecting into the body cavity; completely or partially covered by peritoneum.

rhizome An elongate, horizontal subterraneous stem of a seagrass or other plant, producing shoots above and roots below and serving for the storage of reserve food material.

ritualization An evolutionary process through which behavior becomes partly or completely "emancipated" from its original function(s) and acquires new functions for communication. For example, vocalizations presumably represent ritualized breathing.

riverine Living in rivers; found in or relating to a river.

rookery A terrestrial breeding area used by a colony of pinnipeds on a seasonal or permanant basis. (From an earlier use of the term to describe the breeding or nesting area of a large number of rooks, a crowlike bird of Europe.)

rooster tail A spray of water formed when certain small cetaceans surface at high speed; caused by a cone of water coming off the animal's head. (So named because the form of the spray resembles a rooster's feathers.)

rorqual Any of six species of baleen whales (the minke, blue, humpback, fin, Bryde's, or sei whale) belonging to the family Balaenopteridae, characterized by a variable number of pleats that run longitudinally from the chin to near the umbilicus. The pleats expand during feeding to increase the capacity of the mouth.

rostral Having to do with the nose or head; toward the front.

rostral hairs Small hairs on the outside edge of the rostrum of a cetacean.

rostrum The beak-like projection found at the front of the skull or head of a cetacean; the term also refers to the skeletal support of the upper jaw, comprising the anterior parts of the maxillary, premaxillary, and vomerine bones of the skull.

r-selection The reproductive strategy of a species that tends to grow quickly and have a large number of offspring, but that has a relatively short life span and negligible parental involvement in the rearing of young. Certain insects are cited as an example of r-selection. Contrasted with a k-selected species, which has slower growth and a smaller number of offspring, but a longer life span and significant parental involvement.

ruminant A hoofed mammal that feeds by grazing or browsing; it has a complex four-chambered stomach (**rumen**) and thus is able to regurgitate and then rechew its food (i.e., it "chews its cud"). Ruminants include domestic cattle, sheep, goats, deer, antelopes, and giraffes.

S

sacral vertebrae Vertebrae associated with the pelves; a feature that is not present in cetaceans and manatees.

school An aggregation of fish or other animals that regularly swim together as a unit.

scotoma An area of diminished vision within the visual field.

scotopic vision Vision in conditions of dim luminance.

scramble competition A mechanism of sexual selection in which males compete for access to females by searching and locating females more efficiently than their rivals. Females may mate with one or several males.

sea cow A strictly marine herbivorous mammal foraging near the surface, primarily on large marine algae, and propelling itself with a triangular caudal fluke. The term is also used loosely for any member of the order Sirenia.

seagrass(es) Any of various marine flowering plants belonging to the families Potamogetonaceae and Hydrocharitaceae, consisting of 12 genera and some 50 species.

sea ice Frozen seawater, which forms ice floes (i.e., pack ice).

seal bomb An explosive noise-making device designed to chase marine mammals away from areas where they are regarded as harmful to fisheries, nets, and so on.

seasonality The fact of being affected by or dependent on a change of seasons; e.g., changes in population distribution that are related to changes in seasons.

sebaceous glands Glands located at the base of mammalian hairs that release an oily secretion, sebum.

secondary sexual characteristic A feature of a male or female animal that is produced as sexual maturity occurs.

sedimentology The scientific study of sediments, solid fragmentary material transported and deposited by wind, water, or ice, or precipitated from solution, or secreted by various organisms.

selection The evolutionary process favoring individuals with genotypes that enable them to raise the greatest number of young which survive to breed.

selection coefficient A mathematical term indicating the decrease in disfavored gene types contributed to the next generation; e.g., a selection coefficient of 0.5 for a given genotype indicates a decrease of 50% of that genotype entering the next generation.

semiaquatic Only partly aquatic, e.g., an animal that forages for food in water but otherwise lives and breeds on land.

seminiferous tubules Convoluted loops within the testis where spermatozoa are formed.

sensillum A sensory receptor or a receptor complex in the cuticle of an invertebrate.

sensitization An increased behavioral (or physiological) responsiveness occurring over time, as an animal learns that a repeated or ongoing stimulus has significant consequences. Cf. HABITUATION.

sensor A device that reacts to a certain physical stimulus in a quantifiable manner.

sensory adaptation The lessening of a response to a stimulus due to physiological fatigue.

sentience The ability to sense; in particular, the capacity to experience pleasure and pain.

serial carpus and tarsus An arrangement of the carpal and tarsal bones in a serial way; i.e., the pattern of relations between carpal and tarsal bones is "pillar-like." Each bone of the first row articulates mostly with only one bone just under. This is a derived condition compared to the generalized mammalian condition. Cf. ALTERNATING CARPUS AND TARSUS.

sessile Stationary or fixed, e.g., plants growing on the sea floor or mussels attached to rocks.

sex chromosomes Nuclear chromosomes that are involved in sex determination, e.g., the X and Y chromosomes in mammals.

sexual bimaturation The sexual maturing of one sex significantly earlier than the other.

sexual dimorphism The development of physical and other differences between the sexes of the same species, especially when this difference extends beyond the reproductive organs to overall size, color, and the development of special features; e.g., male elephant seals are vastly larger than the females, with enlarged canine teeth, and thickened skin for fighting other males in competition for mating opportunities.

sexual selection Selection due to the advantage some individuals have over others of the same sex in exclusive relation to reproduction. This may lead to the evolution of costly secondary sexual characters found only in one sex (such as a male peacock's tail or a stag's antlers), which may decrease the probability of survival and which therefore is opposed by natural selection.

shelf A sea zone located close to land and having the same geological structure. A shelf zone is 100–200 m deep.

sibling species A species that is morphologically very similar to another, sometimes to the point of seeming identity, but demonstrated to be a separate species on the grounds of genetic, behavioral, or cryptic morphological evidence.

sister group The closest relative with which a taxon has a common ancestor.

site fidelity The tendency to return to mate at the same site repeatedly in different breeding seasons. This term is used instead of PHILOPATRY if the animal's original birth site is not known.

size index An analog of the ENCEPHALIZATION INDEX, related to single brain components rather than the total brain.

small-type whaling Japanese coastal whaling that uses a vessel and cannon of small size. Operated since the beginning of the 20th century for minke and toothed whales (other than sperm whale); came under the control of the Japanese government in 1947.

soak time A term for the length of time that a piece of fishing gear such as a gill net is left in the water to fish.

social learning The social transfer of information and skill among individuals by processes that include imitation, teaching, exposure, social support, matched dependent learning, stimulus enhancement, observational conditioning, and goal emulation.

somersault A behavior involving an acrobatic stunt in which the body rolls in a complete circle, head over heels, or, in the case of dolphins, head over tail.

sonar **1.** An acoustic system or device that emits sound into water or another medium, detects echoes received from objects, and processes those signals to characterize and/or visualize the objects. **2.** In marine mammals, a means of detecting, identifying, and tracking prey by the emission of sound pulses and the analysis of the resulting echo patterns.

song Among marine mammals, a series of sounds repeated in a specific pattern.

sonic lens An anatomical structure that focuses sound as optical lenses focus light, e.g., the melon of odontocete whales.

sound A form of energy manifested by small pressure variations in a medium (such as water or air). Depending on the strength and frequency of the sound, it may be detectable by an organ of hearing.

source level The acoustic pressure that would be measured at a standard distance (usually 1 m) from a point source radiating the same amount of sound as the actual source.

spectral sensitivity Selective sensitivity of visual receptors to a certain region of the light wavelength spectrum that corresponds to different light colors.

spectrogram A graphic representation of sound waves per unit of time.

spermaceti A white, translucent substance, obtained from the distinctive form of oil made of wax esters and triglycerides that is found in the spermaceti organ of sperm whales.

spermaceti organ An elongated, barrel-shaped structure making up much of the sperm whale's head, made of soft spongy tissue filled with spermaceti oil.

spermatogenesis The process by which sperm develop and mature from primitive sperm cells (spermatogonia and subsequently spermatids).

spermatophore A collection of spermatozoa enclosed in a sheath of gelatinous material.

sperm competition A mechanism of sexual selection in which a female mates with more than one male, and males compete to fertilize her eggs by producing more sperm per ejaculation, or by mating with her more frequently than their rivals.

sphincter A muscle that forms a ring and contracts upon itself.

splanchnic Pertaining to the viscera, such as the liver, stomach, and pancreas.

sporta perimedullaris A sheet-like structure of connective tissue and muscle that lies between the renal cortex and the medulla.

spout A term for a cloud of vapor and sea water mixed with air that is exhaled by cetaceans.

sprint A high-speed, maximum effort or movement of short duration.

spyhopping A behavior that involves raising the head vertically out of the water, then sinking below the surface without much splash.

stable isotope An alternate form of an element that is more persistent than the common form.

statistical power The ability of an analysis to correctly reject the null hypothesis, i.e., not to miss a real effect.

stem group One extinct species, or several extinct species, that form an extinct sister group, or sequence of sister groups, to the crown group.

stereoscopic vision A capability of vision to discriminate the distance to an object based on a small difference of images (disparity) projected on the retinae of two eyes. This ability requires binocular vision.

stereotyped behavior A pattern of repetitive movements, such as pacing back and forth or swaying to and fro, that often are performed by captive animals held in impoverished environments, and that are not associated with any behaviors normally performed by these animals in the wild.

stochasticity A random occurrence of events in space and/or time; random variability.

stock A group of animals of the same species or smaller taxa, existing in the same locale and interbreeding when mature.

stored reserves Body components that are supplementary to immediate requirements, most often of fat and blubber.

stranding A situation in which a marine mammal is helpless. This generally refers to an animal that comes ashore accidentally or because of injury or illness.

strandling A term for any marine animal that cannot cope with its immediate situation, either ashore or at sea (e.g., a beached whale, an Arctic seal in Florida waters, or a sea otter drenched with oil).

strategy Genetically distinctive rules for individual behavior. Selection favors the strategy that yields the highest reproductive success in relation to competing strategies.

stratification A vertical density gradient caused by changes in temperature and salinity with depth.

streamlining Body shape that causes little distortion to the fluid flow around it and minimizes drag.

striated muscle The skeletal or locomotor muscles of the body.

strip transect sampling A sample count method in which counts are conducted within long, narrow strips.

subarachnoid space A space under the arachnoid membrane, one of the coverings of the brain.

subarctic Living in an intermediate zone between arctic and temperate waters.

subspecies A formally described and named geographic entity within a species.

supraoccipital A bone at the top of the rear of the skull.

surface-active group A group of right whales, typically consisting of one female and one to many males, engaged in vigorous physical interactions at the surface, which appear to be courtship or other social behavior.

surfing The behavior of riding on a wave or waves. There are two basic patterns: floating on top of the water and falling down the advancing edge of a wave or riding within a wave being created by water being pushed upward by the movement of a denser medium (such as a whale or vessel). Dolphins engage in both types of surfing or "wave riding."

survival rate The probability of an animal remaining alive over a given time period; typically expressed as the proportion of individuals in a population surviving from one period (usually defined as a year) to the next.

sustainability **1.** The combined capacity of a system and its parts to retain their interactions and other natural qualities. **2.** Specifically, the level of human activity in a given ecosystem that can continue without degrading the ecosystem or seriously depleting resources.

sustained swimming Long duration activity generally performed at low speeds.

sympatric Occurring together geographically; coexisting in the same place.

sympatry **1.** The fact of occurring or living in the same geographical area. **2.** Specifically, the existence of two or more populations of closely related species in identical or broadly overlapping geographical areas.

symphysis The merging of two bones.

synapomorphic Sharing a derived character state.

synapomorphy A shared derived character that is the result of common ancestry.

synonymous mutations Single nucleotide substitutions that do not result in amino acid replacements.

systematics **1.** A method of classifying organisms that strives to establish its categories on the basis of evolutionary history and relationships. **2.** The scientific study of such evolutionary relationships.

systemic Broad or universal in application while accounting for everything of importance in proportion to its importance; applying to, and accounting for, complexity.

systole The period of ventricular contraction during the contraction–relaxation cycle of the heart.

T

tachycardia A heart rate above the resting rate.

tag Any artificial mark attached to animals.

tail-slapping Another term for LOBTAILING, sometimes used when referring to dolphins.

taxon *plural*, **taxa** A natural grouping of related organisms, usually named, and of a given rank (e.g., order, family, genus, species, subspecies).

taxonomic(al) Based on or describing the classification of organisms according to species or higher levels.

taxonomy The science of classifying organisms into species, genera, and higher categories.

telemetry The measurement of biological data through transmission or reflection of sound waves or radio waves from an animal to a distant receiver.

telescoping A term for the derived condition in both mysticetes and odontocetes wherein the cranial bones of the rostrum extend posteriorly over the facial region and the bones of the occiput thrust forward toward the cranial vertex.

telson An unpaired terminal abdominal segment of crustaceans.

temporal fossa A cavity or depression in the pair of compound bones that form the sides and base of the skull.

temporary threshold shift A temporary impairment in hearing capability caused by exposure to strong sounds.

tension The partial pressure of a particular gas in solution.

terrestrial On land; occurring or living on land rather than in water or in the air.

territorialism The fact of establishing and defending a territory (see below).

territory A certain roughly delineated area that is aggressively defended by an individual or group against intruders of the same or different species; e.g., a breeding ground that adult males maintain by challenging, threatening, and fighting other males, and in which they mate without harassment from other males.

Tertiary A period of geological time from about 65 million to 2 million years before the present day.

testosterone The primary male hormone, produced in the testis.

teutophagous Feeding on squid.

thelycum A female organ to which spermatophores are attached with a sticky fluid.

thermal insulator A material, such as fur or blubber, that serves to retain heat in an animal.

thermocline In seawater, a steep vertical temperature gradient below a well-mixed surface layer.

thermohaline Relating to the temperature and salinity of seawater.

thermoneutral Falling within the range of temperatures at which thermoregulation can be maintained.

thermoneutral zone The range of environmental temperatures at which an animal does not require an increase in metabolism to maintain its body temperature.

thermoregulation The control of body temperature through the balance of heat production and loss; the ability of an animal to regulate its body temperature.

thoracic Describing the region within the thorax, or the portion of the vertebral column within the thorax.

thoracic vertebrae Rib-bearing vertebrae.

thorax The part of the vertebrate body that contains the heart and the lungs, in mammals divided from the abdomen by the diaphragm.

threatened A designation for a species that is likely to become endangered within the foreseeable future throughout all or a significant portion of its range in the wild.

time-activity budget A quantitative description of the amount of time spent by animals in different behavioral activities. Energetic costs of different behavioral activities are used to construct such budgets.

time-depth (time-data) recorder A mechanical or electronic instrument that measures and stores information on the diving and swimming behavior and environmental variables of aquatic mammals, birds, fish and turtles.

toothed whale See ODONTOCETI.

tooth replacement The shedding of deciduous (or milk) teeth followed by the eruption of permanent teeth.

top-down control The consumer-mediated regulation of the structure and function of an ecological community.

transient killer whales A population of killer whales found in coastal waters of the northeastern Pacific that is sympatric with residents and offshores, but socially and reproductively isolated from them, and genetically distinct. Transients feed preferentially on marine mammals and seabirds.

transport host A host infected by a larval parasite stage in which the parasite survives, and can be transmitted to another host, but does not develop. Transport hosts are not required to complete the life cycle but enhance the chances of transmission to the definitive host.

transverse septum A membrane that functions as a separator between the heart and the liver.

trawl A bag-like net that is dragged through the water in order to catch fish.

trematode Any parasitic flatworm of the class Trematoda, especially a fluke, equipped with hooks or suckers.

triglyceride An ester of glycerol that is combined with three fatty acids. It is the primary chemical form in which lipids are stored in the tissue.

trophic Relating to the process of feeding or feeding patterns.

trophic cascade Interactions among trophic levels through top-down control.

trophic flows The transfer of food or energy between the different groups of species comprising a food web.

true seals See EARLESS SEALS.

trying down The traditional practice of cooking blubber to extract the valuable oil; rendering.

tubercule **1.** One of a series of small, raised epidermal protuberances found on the dorsal fin of most porpoise species. Their distinctness, density, and covering area vary among species. **2.** A knob-like structure of unknown (but probably sensory) function, found on the head and jaws of humpback whales. Each tubercle contains a single hair (vibrissa).

tumor A swelling, especially from an abnormal growth of tissue.

tuna purse seine See PURSE SEINE.

tunica albuginea A white fibrous layer covering an anatomical structure.

tunicate A member of a subphylum of chordates containing the classes Ascidiacea (the sessile sea squirt), the free-swimming tadpole-like Larvacea, and the Thaliacea (free-swimming salps). Chordate features (i.e., notochord and nerve chord) are found only in larva and are generally lost in the adult. The adult secretes a tough cellulose sac (tunic) in which the animal is embedded.

turbid Exhibiting reduced water clarity because of the presence of suspended matter.

turbulent flow An unsteady and eddying flow of water. Turbulent boundary layers are thicker than laminar boundary layers and likely to separate prematurely.

tympanic cavity A large, irregularly shaped cavity of the middle ear.

tympanoperiotic earbones Very dense bones at the base of the skull consisting of the ventral ectotympanic bone or bulla, which encloses the middle ear cavity, and the more dorsal periotic or petrosal bone, which contains the cochlear apparatus of the inner ear and the balance organ (vestibulum plus semicircular canals). The structure of tympanoperiotic bones is used widely to indicate taxonomic relationships of both extant and fossil cetaceans.

U

ugruk Northern Alaskan Inuit term for a bearded seal.

ultimate explanation See PROXIMATE EXPLANTION.

ultrasonic Describing acoustic signals that are above the normal human range of hearing.

ultrasonography The visualization of deep structures of the body by recording and displaying the echoes of pulse of ultrasonic waves directed into the tissues.

ultrasound **1.** A sound that is higher in frequency than the maximum audible to humans, usually said to be 20 kHz. Many marine mammals can hear ultrasound. **2.** see ULTRASONOGRAPHY.

umialik Northern Alaskan Inuit term for a whaling captain.

umiaq *plural*, **umiat** Northern Alaskan Inuit term for a skin boat used to hunt whales, seals, and walrus.

underhair A layer of shorter, finer hair that provides better insulation than the longer, thicker hair (called guard hairs) covering it.

ungual Having claws; claw-bearing.

ungulate Any of a taxonomic group (Ungulata) comprising the hoofed mammals and their derivatives, including the living Artiodactyla, Cetacea, Perissodactyla, Hyracoidea, Sirenia, and Proboscidea, together with the extinct Desmostylia and numerous other fossil groups.

unguligrade Referring to limbs that are elongated and slim with an efficient fore-and-aft drive and nearly no capability of rotating. Unguligrade limbs are typical of ungulate mammals.

upwelling A process by which ocean water rises from a deeper to a shallower level, usually by divergence and offshore currents. This process often occurs along the edges of continental shelves and brings nutrient-rich water to the surface.

ureter The duct that carries urine from the kidney to the urinary bladder.

urethra A duct or canal in the penis through which urine and semen are transported.

uropod Fan-shaped paired appendages on the penultimate segment of euphausiids, used for swimming.

Ursidae A family of arctoid carnivorans that includes the subfamilies Ursinae, Hemicyoninae, and Amphicynodontinae, the latter two being represented only by fossil taxa.

V

vacuole A fluid-filled space in a cell, usually small in animal cells; several vacuoles coalesce in the developing follicle to produce the antrum.

vascular Describing the system of vessels in the body that carry blood. The arteries, veins, and capillaries are part of the vascular system.

vasculitis The inflammation of a blood vessel.

vasopressin A peptide hormone (antidiuretic hormone) that is released from the posterior pituitary gland. It increases the permeability of the collecting duct, thereby suppressing urine formation and output.

venae cavae Major veins returning blood from the periphery to the heart.

ventral Toward the front; in anatomy, toward, or relatively near to, the belly and the corresponding surface of the head, neck, thorax, and tail.

ventral grooves A series of parallel grooves or pleats running longitudinally on the undersurface of the throat and chest region in balaenopterid whales, allowing great expansion of the mouth during feeding.

vertebra *plural* **vertebrae** A bone of the spine; a back bone.

vertebral canal The space within the vertebral column that houses the spinal cord.

vertebral column The row of bones forming the longitudinal axis of the body; the backbone.

vertebrate One of the Vertebrata, the subpyhlum including those animals having a backbone; i.e., fish, amphibians, reptiles, birds, and mammals.

vertex An elevated conjunction of the nasal, frontal, and supraoccipital bones at the top of the skull.

vestigial tooth A tooth that has no function in food processing. Usually these teeth do not erupt out of the jawbone or do not break through the dental gums.

vibrissae Large, tactile, sensory hairs present on the upper lip of mammals.

vicariance event The development of a natural biogeographical barrier causing groups that previously occupied the same area or adjacent areas to become physically separated.

vicariant Describing a major geological or oceanic split in habitat, such as the geological closure of a strait, thus splitting distributions of many organisms.

vicariant speciation Evolution of species triggered by fragmentation of the ancestral species' distribution area.

villus A finger-like anatomical projection that increases the surface area greatly and facilitates exchange between two media (e.g., the surface of the small intestine and its contents) or tissues (e.g., the maternal and fetal parts of the placenta).

visual acuity Sharpness of vision; the capability to discriminate visual pattern details.

vital rate Any of various key indicators describing the dynamics of animal populations, including birth rates, recruitment rates, mortality rates, immigration, and emigration.

vomeronasal organ An organ for chemical reception situated in the anterior part of the roof of the mouth; anatomically and functionally distinct from the senses of smell and taste; well developed in many species of mammals, in which it is especially important in reproduction.

vortex The rotating motion of a fluid around a central core.

vulnerable A designation for a species that is not regarded as critically endangered or endangered at present, but that is facing a high risk of extinction in the wild in the medium-term future.

W

weaning The end of the lactation period; the process of changing from milk to a solid diet in juvenile mammals.

whale A term commonly used for a subset of the mammalian order Cetacea. In general, it includes the larger members of the order, but the term is inconsistently used for animals of vastly different sizes that are not closely related. In some cases, it refers to the Great Whales, i.e., the baleen whales and the (unrelated) sperm whale. Others use whale to include larger members of the dolphin family (such as the killer whale). In that usage, some larger dolphins (such as the bottlenose dolphin) are well above the smallest whales (such as pygmy sperm whales) in size. Paleontologists use the word whale to describe all Eocene forms (some of which are no larger than a dog) and many modern cetaceans. Thus the term whale is scientifically imprecise, and subjects relating to it can be found in this work under more specific headings.

whalebone See BALEEN.

whale louse *plural*, **whale lice** An amphipod crustacean of the family Cyamidae; adapted for living in crevices and other secure places on the skin of cetaceans, on which whale lice largely feed.

whelping The process of giving birth; used to refer to seals.

windkessel A capacitance blood vessel, which due to elastic properties in its wall, first expands and accepts blood volume on blood entry and then passes blood onward due to recoil within its wall.

X

xenobiotic **1.** A chemical compound that is foreign to biological systems, especially one that is toxic. **2.** Relating to or describing a compound of this type.

Z

ziphiid Any of at least 19 extant species of beaked whale, of the family Ziphiidae.

zona glomerulosa The outermost layer of the adrenal cortex principally responsible for the production of the mineralocorticoid aldosterone.

zoonosis *plural*, **zoonoses** **1.** A disease of animals that is transmittable to humans. **2.** The process of disease transfer from animals to humans.

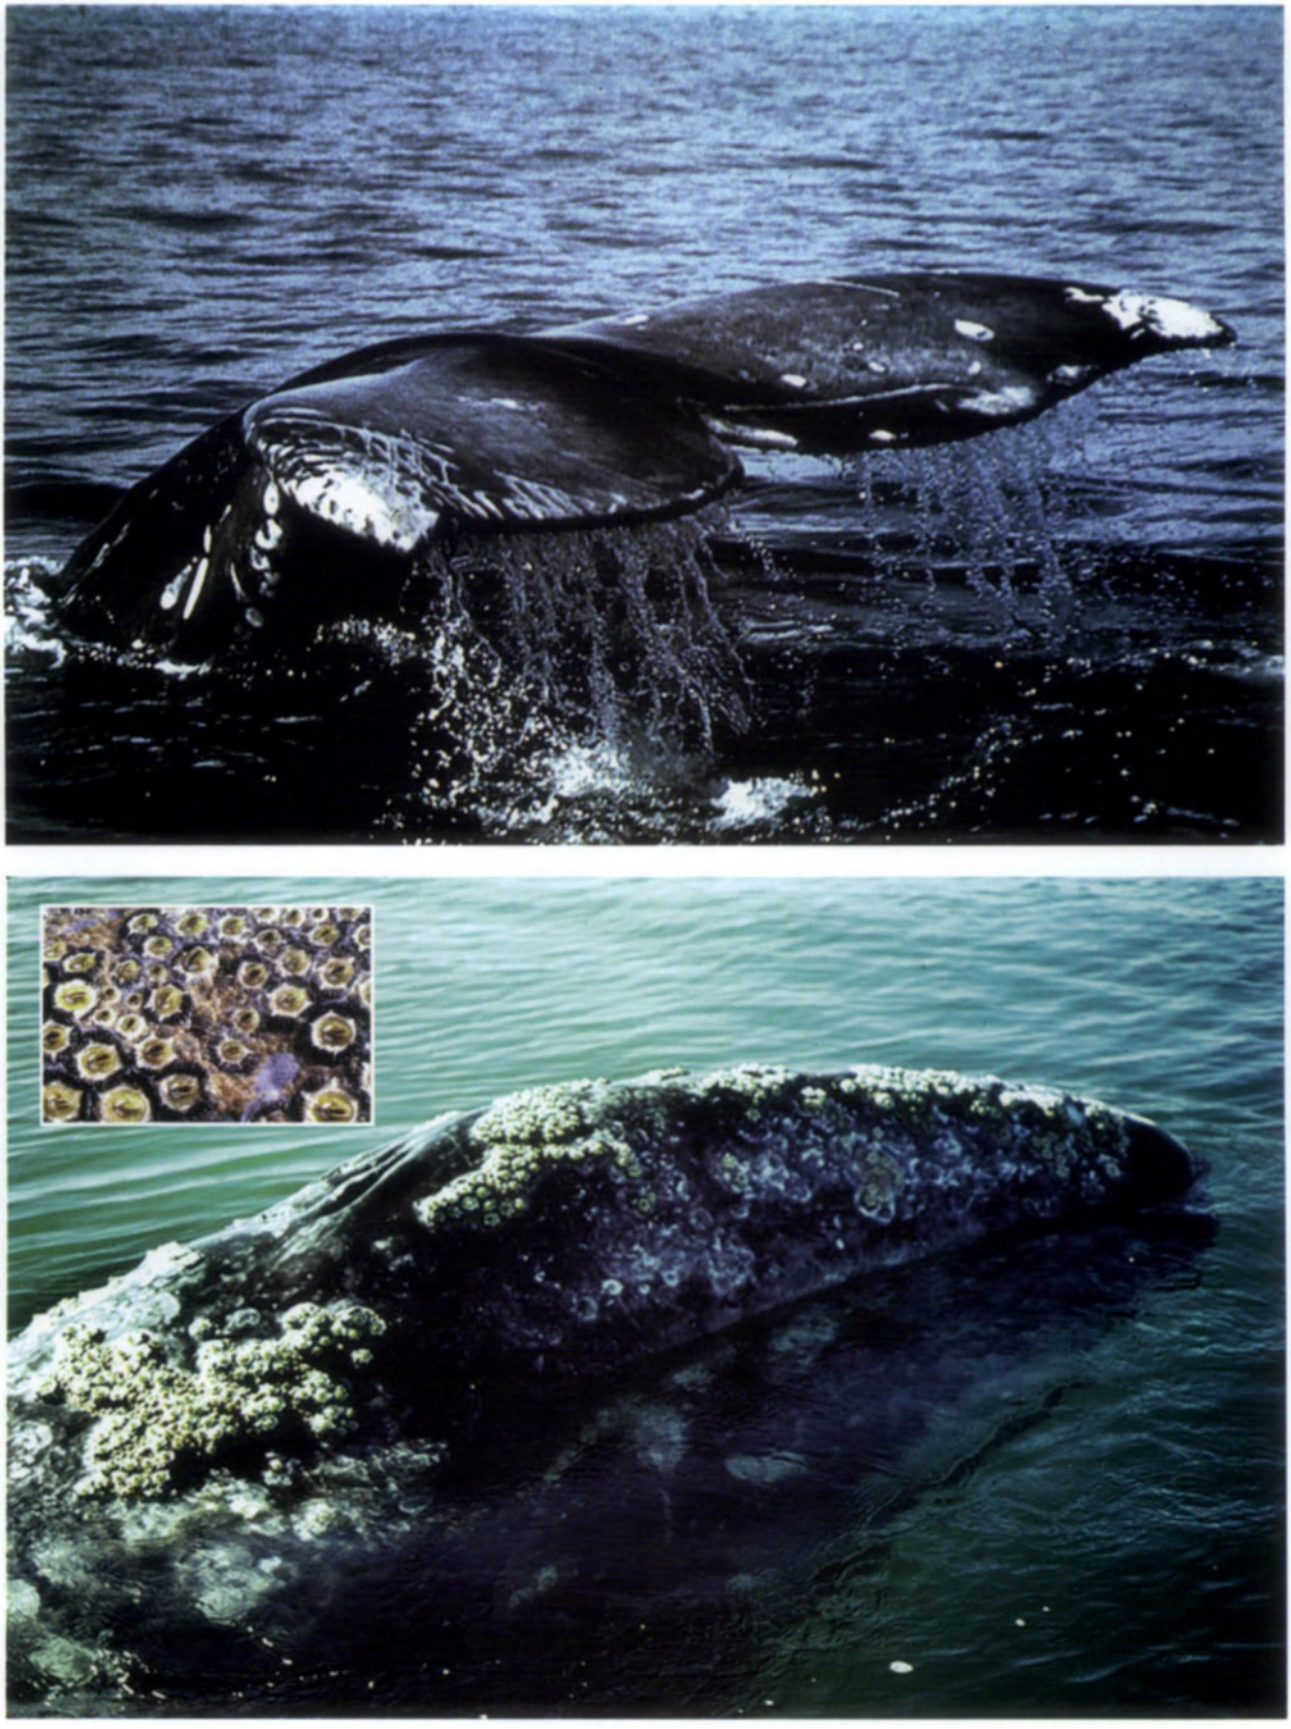
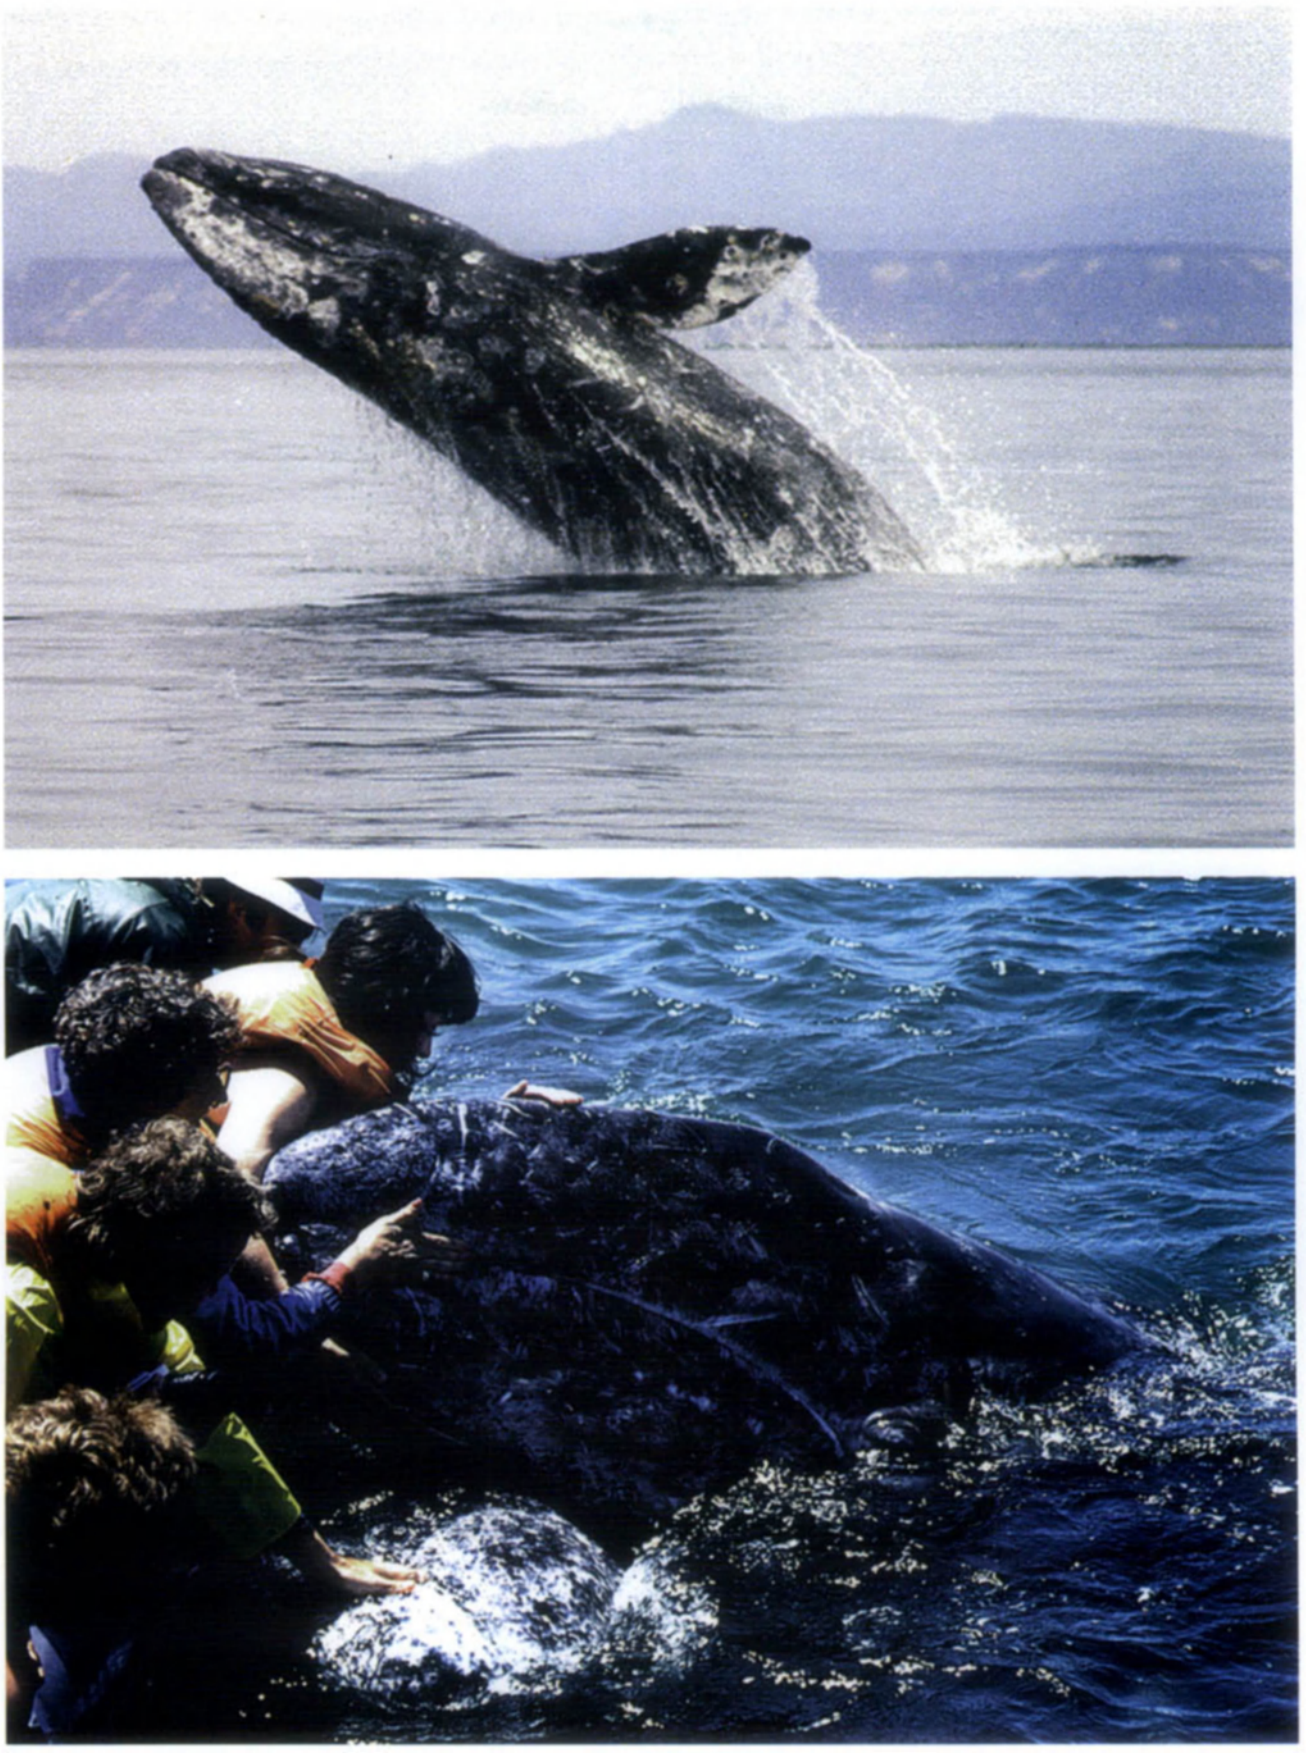
The towering blow of a blue whale (Balaenoptera musculus). *(Photo courtesy of Phil Colla.) See article BLOWING.*

*Top: Aggregations of beluga whales (*Delphinapterus leucas*) interacting and rubbing on the substrate of a shallow estuary during the summer molt. (Photo by Flip Nicklin.) See article BELUGA WHALE. Bottom: Cephalorhynchus dolphins (*Cephalorhynchus *spp.) are among the smallest dolphins. The four dolphins of this genus are found only in Southern Hemisphere waters. (Photo by Steve Dawson.) See article CEPHALORHYNCHUS DOLPHINS.*

Top: Recently born ringed seal (Pusa hispida) *pup, showing lanugo (fetal covering of fur). See article COLORATION. Bottom: Crabeater seal* (Lobodon carcinophaga)*; most crabeater seals possess long, raking scars on their torsos resulting from attacks in their first year of life by leopard seals. (Photo by John L. Bengtson.) See article CRABEATER SEAL.*



Top: A team from the Center for Coastal Studies in Provincetown, Massachusetts, attempts to cut away fishing line wrapped around the tail of a right whale in Cape Cod Bay. Specially designed knives are deployed at the ends of long poles. The men are wearing helmets as a precaution while undertaking this dangerous work. (Photo courtesy of Center for Coastal Studies.) Bottom left: An Indus river dolphin that had been marooned in an irrigation canal is released back into the main river channel upstream of Sukkur, Sind Province, after being rescued by a team of conservationists from Sind Wildlife Department and WWF-Pakistan. (Photo courtesy of World Wide Fund for Nature-Pakistan.) See article CONSERVATION EFFORTS. Bottom right: When a marine mammal strands, the public effort to provide assistance is typically immediate and highly committed. (Paul H. Forestell/Pacific Whale Foundation.) See article POPULAR CULTURE AND LITERATURE.



Top: California sea lions often move into a purse seine net to start feeding before the net is pursed, and continue to feed until all the fish are pumped aboard the fishing vessel. (Photo by Jon Stern.) See article FISHERIES, INTERFERENCE WITH. Bottom: A harbor porpoise entangled in a cod gillnet in the North Sea, one of several thousand dying this way each year in European gillnet fisheries. (Photo by Nigel Godden/Sea Mammal Research Unit.) See article INCIDENTAL CATCHES.

*Top: The flukes of the gray whale (*Eschrichtius robustus*) are over 3 m wide, frequently bear scars from the teeth of killer whales, and are often lifted before a deep dive. Bottom: The gray whale's narrow head is usually covered with patches of barnacles. Inset: Dense clusters of barnacles surrounded by whale lice develop shortly after birth. Barnacles leave white scars on the whale's skin that slowly re-pigment over time. See article GRAY WHALE.*

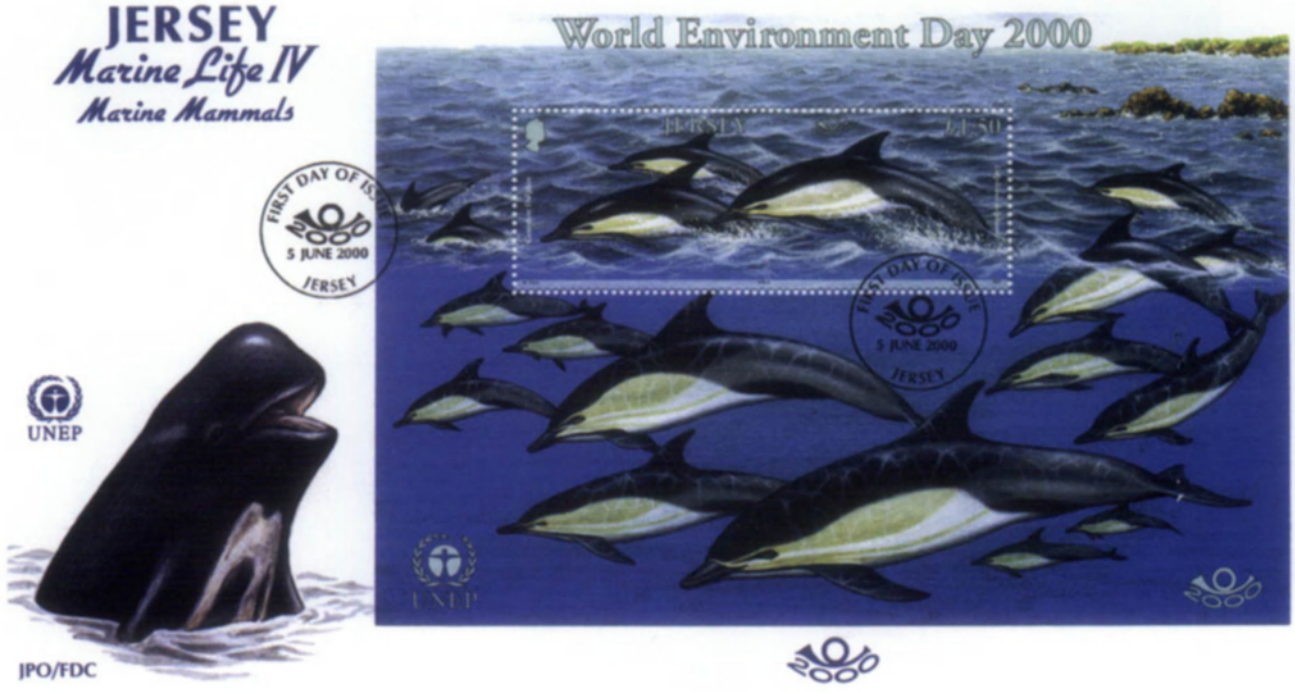
Top: Gray whales breach frequently while migrating and at their winter breeding grounds. One animal was observed to breach 40 consecutive times. Bottom: A "friendly" gray whale cow and calf allow whale watchers to pet them (note the tip of the female's lower jaw in the foreground). (Gray whale photos © Mary Lou Jones and Steven L. Swartz.) *See article GRAY WHALE.*

*Top: Killer whale (*Orcinus orca*) attacking a gray whale calf. (Photo by Sue Flood/BBC Natural History Unit on Marine Mammals.) See article PREDATION ON MARINE MAMMALS. Bottom: Communal hunting pattern allows dolphins to combine pursuing efforts. (Photo © Alejandro Acevedo-Gutiérrez.) See article GROUP BEHAVIOR.*

Dugongs (Dugong dugon) *preferentially feed on below-ground portions of seagrasses, creating a cloud of sediment during their foraging activity. (Photo by Michael R. Heithaus.) See article FEEDING STRATEGIES AND TACTICS.*

Top: A female sea otter (Enhydra lutris) *with her pup. See article OTTERS. Bottom: The polar bear,* Ursus maritimus, *is aptly named, as members of the species are often observed miles from the nearest land on polar pack ice and swimming between ice floes, where they hunt ringed seals and sometimes bearded seals. (Photo by François Gohier.) See article POLAR BEAR.*

*Top: California sea lions (*Zalophus californianus*) are highly polygynous and form dense aggregations on rookeries commonly found along the shoreline at breeding sites on the California Channel Islands. Bottom left: Adult male California sea lions compete for territories at San Miguel Island, California. Bottom right: A much larger and darker adult male attempts to block an adult female from leaving his territory at San Miguel Island. (Photos courtesy of George Antonelis, NMFS.) See article ROOKERIES.*



Top: Female New Zealand fur seal (Arctocephalus forsteri). *(Photo by John Arnould.) See article SOUTHERN FUR SEALS. Bottom: A weaned hooded seal* (Cystophora cristata) *pup 4 days old, reported as weighing 44 kg. See article EARLESS SEALS.*

A false killer whale (Pseudorca crassidens) *displays the typical fusiform body that aids the cetacean in locomotion. See article STREAMLINING.*

Whales and dolphins have become emblematic of the diversity and health of marine ecosystems and therefore have found their way onto the stamps of nations wishing to celebrate the sea and promote conservation. Examples are the many marine-mammal stamps and souvenir sheets issued during the UNESCO International Year of the Ocean in 1998, by the United Nations and a large number of its member countries; some are shown here. Series of colorful stamps showing wildlife are popular with topical collectors in general and provide important revenue for small, less-developed countries and subnational entities; an example is the whale and dolphin series issued in 2000 by Jersey (below), actually part of the UK but authorized to issue its own stamps. The current trend is toward attractive souvenir sheets showing species in their natural environments (for example, the Irish souvenir sheet on facing page, top). Whaling history has also become a popular topic (see souvenir sheet from Tristan da Cunha). Collecting (and using) these stamps contributes to public awareness of marine mammals, highlighting their diversity, beauty, grace, and conservation problems.

*Top: An adult male Pacific walrus (*Odobenus rosmarus*). Note the large diameter of its tusks, the bulging eye, which is turned to look backward, and the prounounced tubercles of the skin on the neck. The last feature is seen only in adult males. Bottom: A large group of male Pacific walruses on Round Island, Bristol Bay, Alaska. Note how closely the animals are packed together. (Photos by Steve Rice, U.S. Fish and Wildlife Service.) See article WALRUS.*

ENCYCLOPEDIA OF
MARINE MAMMALS

Editors

WILLIAM F. PERRIN Southwest Fisheries Science Center, NOAA
BERND WÜRSIG Texas A&M University
J. G. M. THEWISSEN Northeastern Ohio Universities College of Medicine

The ***Encyclopedia of Marine Mammals*** is a comprehensive, scientifically accurate work devoted to all aspects of marine mammals, including their anatomy, physiology, evolution, behavior, reproduction, ecology, and disease, as well as issues of exploitation, conservation, and management. Special emphasis is given to marine mammal interaction with humans. Articles provide definitive facts about seals and sea lions, whales, dolphins and porpoises, and manatees and sea cows, as well as sea otters and polar bears. Each article is authoritative and up-to-date, prepared by one or more internationally recognized experts on the topic. In addition to providing information for scholars and researchers, the entries offer material for a high school or university level student, or even an interested general reader.

The Encyclopedia includes the following features:

- Over 1,400 pages of informative articles arranged alphabetically for convenient location of information
- 283 separate articles commissioned especially for this volume and thoroughly peer-reviewed for accuracy
- Articles written by the leading authorities on marine mammology from 20 different countries around the world
- 840 figures and tables to support and amplify the written text, including 16 pages of special color plates
- 1,700 cross references within the articles, providing links to other articles elsewhere in the book that amplify the subject at hand or give information about a related subject
- Approximately 3,000 bibliography entries that accompany the articles, presenting sources chosen by the authors to provide additional material on the article topics
- Extensive appendix including biographies of famous scientists, definitive list of all marine mammal species, and glossary of more than 1,000 terms
- Comprehensive subject index that directs the reader to specific subjects discussed within the articles

This volume is the latest in the highly successful series of one-volume encyclopedias from Academic Press. Previous titles include ***Encyclopedia of Dinosaurs*** and ***Encyclopedia of Volcanoes,*** each of which has won three different awards for publishing excellence. Additional resources and information can be found at the Encyclopedia Web site: www.academicpress.com/narwhal/
